This question tests your understanding of disease prevalence, and the relative importance of certain symptoms and signs in differentiating disease. Patients rarely present with the classical textbook descriptions of symptoms. From the options given above osteoarthritis is the MOST LIKELY diagnosis.

[Q: 3390] OnExamination 2012 - Rheumatology

Which of the following is commonly associated with psoriasis?

- 1- Angular stomatitis
- 2- Koebner phenomenon
- 3- Optic neuritis
- 4- Response to chloroquine
- 5- Scarring alopecia

Answer & Comments

Answer: 2- Koebner phenomenon

Psoriasis is a chronic relapsing inflammatory skin disorder most commonly characterised by erythematous, sharply demarcated papules and rounded plaques covered by silvery scales. Diagnosis is usually clinical, and skin biopsy is rarely required to confirm psoriasis.

New lesions often appear at sites of injury or trauma (Koebner phenomenon), which typically occurs one to two weeks after the skin has been damaged.

Psoriasis can be associated with an anterior uveitis, but optic neuritis is not a recognised complication.

Angular stomatitis describes erythema and fissuring of the skin adjacent to the angle of the mouth. The most common cause is Candida infection, but it is also associated with allergy, seborrhoeic dermatitis, vitamin B deficiencies and iron deficiency. It is not commonly described in association with psoriasis.

The scalp is often involved in psoriasis, especially in children and adolescents. Most commonly it causes a telogen effluvium, that is, the hair follicles are forced into the telogen resting stage.

It is rare for psoriasis to cause a scarring alopecia.

Up to 30% of patients with chronic plaque psoriasis may be affected by an arthropathy. This can range from mild distal interphalangeal joint involvement with nail pitting to severe arthritis mutilans.

Whilst the exact cause is unknown, psoriasis has a strong genetic basis. European populations are commonly affected, and there are two peaks of incidence at 16-22 years and 57-60 years. Males and females are equally affected.

External factors such as infection, stress and medication may exacerbate psoriasis. Some of the common medications associated with

triggering or worsening psoriasis include lithium, gold salts, β -blockers and antimalarials (including chloroquine).

[Q: 3391] OnExamination 2012 - Rheumatology

Which of the following may be responsible for an acute relapse of systemic lupus erythematosus (SLE) in a 38-year-old female?

- 1- Hydralazine therapy
- 2- Pregnancy
- 3- Progesterone only contraceptive pill
- 4- Salmeterol therapy
- 5- Winter holiday in Lapland

Answer & Comments

Answer: 2- Pregnancy

Some physiological and environmental factors affect the periods of deterioration and of remission in systemic lupus erythematosus.

These factors include hormone replacement therapy (HRT) and particularly the oral contraceptive, pregnancy and infection. It would not be expected with the progesterone only oral contraceptive.

You would expect to find virtually no sun on a winter holiday in Lapland (Arctic circle).

A number of drugs (hydralazine, procainamide, isoniazid, chlorpromazine, D-penicillamine and methyl dopa) can result in drug-induced lupus in predisposed individuals.

This can be differentiated from the idiopathic SLE on genetic and immunologic grounds.

Furthermore,

It is mild and reversible on stopping the drug

Renal disease and double stranded anti-DNA are rare (although antibodies specific for histones may be present)

The sex ratio is equal.

These drugs do not cause deterioration in patients with SLE.

[Q: 3392] OnExamination 2012 - Rheumatology

Which of the following is a recognised feature of polymyalgia rheumatica?

- 1- A peak incidence in the fourth decade of life
- 2- An association with bronchial carcinoma
- 3- Elevated serum creatine phosphokinase activity
- 4- Weakness of distal muscle groups
- 5- Weight loss

Answer & Comments

Answer: 5- Weight loss

Polymyalgia rheumatica (PMR) is an inflammatory disease which typically presents with pain and stiffness of the the shoulder and pelvic girdle muscles.

It can have either an acute or subacute onset and is associated with a systemic inflammatory response and therefore constitutional symptoms such as fever, anorexia, weight loss and malaise. Muscle weakness is not a feature of PMR, but this can be difficult to assess in the presence of pain. Due to chronic inflammation, low-grade fever and weight loss are often present. Weight gain is unusual, and peripheral joints are only rarely affected.

The course of the disease is unpredictable, and 30% of patients also have giant cell arteritis.

The cause is unknown, although studies showing a cyclical incidence have led to theories regarding an infectious trigger. Diagnosis of PMR can prove difficult, and

other inflammatory conditions should be excluded.

Patients are usually over 60 years, and PMR is very rarely seen in the under 50s.

Bronchial carcinoma can cause hypertrophic pulmonary osteoarthropathy, which shares some of the features of PMR, but is not a classic association.

Investigations typically reveal:

Normochromic / normocytic anaemia

Raised erythrocyte sedimentation rate (ESR) often > 50 mm/hr (although this may be normal)

Raised C reactive protein (CRP)

Raised creatine phosphokinase would suggest polymyositis rather than polymyalgia rheumatica.

Features of giant cell arteritis should be sought:

Headache

Visual disturbance

Jaw claudication

Thickened and tender temporal arteries.

Response to a moderate dose of steroids can be useful in confirming the diagnosis of PMR. The maximum dose of prednisolone should not exceed 20 mg once daily. Patients should report 70% improvement in symptoms within three to four weeks, and inflammatory markers should have normalised by this point.

In general, non-steroidal anti-inflammatories have little use and are associated with significant morbidity. There is little evidence for the use of steroid-sparing agents.

[Q: 3393] OnExamination 2012 - Rheumatology

An 85-year-old woman presented with

bilateral osteoarthritis of the knees. She had no history of previous gastrointestinal disease.

Which of the following is the most appropriate initial treatment for her?

- 1- Celecoxib
- 2- Dihydrocodeine
- 3- Naproxen
- 4- Paracetamol
- 5- Topical diclofenac.

Answer & Comments

Answer: 4- Paracetamol

The recommendations of the American College of Rheumatology published in Arthritis and Rheumatism 2000, recommend acetaminophen (paracetamol) together with non-pharmacological interventions (exercise, diet) as first line therapy of mild/moderate OA of hips or knees.

[Q: 3394] OnExamination 2012 - Rheumatology

A 30-year-old woman presents with a deep vein thrombosis.

Of note in her past medical history is three early miscarriages.

Investigations revealed:

Haemoglobin 12.8 g/dl (11.5-16.5)

White cell count $3.6 \times 10^9/L$ (4-11)

Platelet count $35 \times 10^9/L$ (150-400)

Select the investigation which is most likely to be abnormal.

- 1- Antiphospholipid antibodies
- 2- Homocystine concentration
- 3- Indium-labelled white cell scan
- 4- Platelet function test
- 5- Protein C concentration

Answer & Comments

Answer: 1- Antiphospholipid antibodies

The combination of thrombophilia, recurrent miscarriage, thrombocytopenia and leucopenia in this patient indicates a diagnosis of antiphospholipid syndrome, probably associated with systemic lupus erythematosus.

Antiphospholipid syndrome is a common cause of acquired thrombophilia and characterised by arterial and/or venous thrombosis and pregnancy mortality in association with circulating antiphospholipid antibodies. These are a heterogeneous group of approximately twenty autoantibodies directed against phospholipid binding plasma proteins. Three of the most clinically important are the lupus anticoagulant, anti-beta-2 glycoprotein I antibodies and the anticardiolipin antibodies. They can be detected either by phospholipid-dependent coagulation test for lupus anticoagulant or ELISA test for anticoagulation and anti-β2GPI antibodies. Antibodies should be demonstrated on at least two occasions separated by 12 weeks. Antiphospholipid syndrome may be primary, or associated with other conditions (such as systemic lupus erythematosus).

Antiphospholipid syndrome is the most important treatable cause of recurrent miscarriage, defined as the loss of three or more consecutive pregnancies. 15% of women with recurrent miscarriage have persistently positive tests for either lupus anticoagulant or anticardiolipin antibodies, compared to 2% with an uncomplicated obstetric history. In future untreated pregnancies, women with recurrent miscarriage and persistently positive anticardiolipin antibodies have a miscarriage rate of 90%. The majority of miscarriages occur between 7 and 12 weeks gestation, and foetuses are typically chromosomally normal.

It is thought the antibodies affect trophoblast invasion and placentation.

Antiphospholipid syndrome is also an important cause of early onset pre-eclampsia and intra-uterine growth restriction.

Aspirin and low-dose heparin is the treatment of choice to reduce the risk of miscarriage in confirmed antiphospholipid syndrome. This combination has been showed to lead to a 70% live birth rate in future pregnancies. Intravenous immunoglobulin can also be used.

Elevated levels of circulating homocysteine increase the risk of developing coronary artery disease, peripheral vascular disease and cerebrovascular disease but they are not commonly associated with pregnancy loss.

An indium white blood cell scan is a nuclear medicine study in which leucocytes are removed from the patient, tagged with Indium-111 and reinjected into the patient. They can then be used to localise areas of infection and inflammation, such as thrombophlebitis and osteomyelitis.

Platelet function studies measure the platelet's ability to adhere and aggregate. They are not particularly reliable or accurate, and therefore do not have a central role in clinical practice.

Protein C is one of the major inhibitors of the coagulation system. Deficiency is associated with an increased risk of venous thrombosis, but not classically an increase rate of miscarriage.

Antiphospholipid syndrome and recurrent miscarriage. Raj RS. J Postgrad Med 2002;48(1):3-4

Antiphospholipid syndrome diagnosis: an update. Visseaux B et al. Ann Biol Clin (Paris) 2001 Aug 1;69(4):411-418

Antiphospholipid antibody syndrome. Sangle NA and Smock KJ. Arch Pathol Lab Med. 2011 Sep;135(9):1092-1096

[Q: 3395] OnExamination 2012 - Rheumatology

Which one of the following drugs works by inhibiting tumour necrosis factor -alpha (TNF α)?

- 1- Cyclosporin
- 2- Infliximab
- 3- Methotrexate
- 4- Montelukast
- 5- Sulfasalazine

Answer & Comments

Answer: 2- Infliximab

Infliximab is a chimeric monoclonal antibody which binds to TNF α , and has been shown to be of benefit in a number of conditions including rheumatoid arthritis. Two other agents also target TNF α : etanercept (human fusion protein which acts as a TNF α receptor blocker) and adalimumab (humanised form of infliximab). There is a risk of reactivation of TB, and patients should be screened for latent disease prior to starting on therapy.

Methotrexate inhibits dihydrofolate reductase and thymidylate synthesis. It can cause myelosuppression and mucositis.

Montelukast works as a leukotriene receptor antagonist and is used as add-on therapy in moderate asthma. It has been associated with Churg-Strauss-like eosinophilic vasculitis and peripheral neuropathy.

Sulphasalazine consists of a sulphonamide molecule and 5-ASA. It is used in the treatment of ulcerative colitis and also as a disease-modifying antirheumatic in rheumatoid arthritis. It can cause gastrointestinal upset, oligospermia, orange discolouration of body fluids and blood dyscrasias.

[Q: 3396] OnExamination 2012 -
Rheumatology

Which of the following most accurately describes the mechanism of action of the bisphosphonates?

- 1- Calcium resorption in the distal tubule
- 2- Fibroblast proliferation in bone marrow
- 3- Improved vascular supply to bone marrow
- 4- Inhibition of osteoclast activity
- 5- Upregulation of osteoblast activity

Answer & Comments

Answer: 4- Inhibition of osteoclast activity

The mechanism of action of farnesyl diphosphate synthase within osteoclasts. In doing this they interfere with geranylgeranylation (attachment of the lipid to regulatory proteins), which causes osteoclast inactivation. This leads to reduced bone turnover, increased bone mass and improved mineralisation.

[Q: 3397] OnExamination 2012 -
Rheumatology

A 27-year-old man presents with fever, urethritis and arthralgia. He is found to have a swollen ankle with a pustular rash on the dorsal aspect of his foot.

What is the most likely diagnosis?

- 1- Disseminated gonorrhoea
- 2- Lyme disease
- 3- Reactive arthritis
- 4- Staphylococcal arthritis
- 5- Tuberculous arthritis

Answer & Comments

Answer: 1- Disseminated gonorrhoea

The most likely cause for this acute presentation is disseminated gonorrhoea -

with a pustular rash on the dorsum of his foot, fever, urethritis and oligoarthritis.

Gonorrhoea is the second most common bacterial STI in the UK after chlamydia. It is caused by *Neisseria gonorrhoeae*, a Gram negative diplococcus. Transmission occurs by inoculation of infected secretions, with a typical incubation period of two to five days.

Primary infection is symptomatic in 90-95% of men, but only 50% of women. It typically presents with urethral or vaginal discharge, dysuria and abdominal pain. Anal and pharyngeal disease is usually asymptomatic. Spread can occur to involve the epididymis, prostate, endometrium and pelvic organs although this is rare (<10%).

Even less common is haematological dissemination, which results in skin lesions, arthralgia, arthritis and meningitis. There is an increased risk of acquiring HIV infection if you are infected with gonococcus.

Culture is the traditional first line diagnosis test, but rapid diagnosis can be undertaken using light microscopy of genital specimens to detect the bacteria.

Increasingly, nucleic acid amplification tests are used but if positive it should be followed by culture to confirm diagnosis and check antibiotic sensitivities. Treatment is with antibiotics depending on local sensitivities.

Lyme disease is caused by a tick-borne spirochaete, *Borrelia burgdorferi*. It is a multisystem inflammatory disease initially characterised by a spreading erythema migrans rash, and can disseminate to the musculoskeletal, neurological or cardiovascular system. Stages of the disease have varying manifestations, but none would fit with the description above.

Reactive arthritis, formally known as Reiter's syndrome, is an autoimmune condition that develops in response to an infection. Classically this is described as a triad of

urethritis, conjunctivitis and arthritis. Precipitating infections include gastrointestinal organisms such as Salmonella and genitourinary infections, especially Chlamydia. Skin rash as described above is not typically present.

Staphylococcus and tuberculosis are both causes of septic arthritis. Patients are often systemically unwell and urethritis would not be expected.

Reference:

National Guideline on the Diagnosis and Treatment of Gonorrhoea in Adults 2005 (pdf)
British Association for Sexual Health and HIV

[Q: 3398] OnExamination 2012 - Rheumatology

A 28-year-old man presented with acute stiffness and swelling of his knees and ankles, and a painful rash on his legs.

The erythrocyte sedimentation rate (ESR) was 86 mm in the first hour (0-15). Chest x ray showed hilar lymphadenopathy.

What is the most likely outcome?

- 1- Chronic arthritis
- 2- Pulmonary fibrosis
- 3- Renal failure
- 4- Skin ulceration
- 5- Spontaneous improvement

Answer & Comments

Answer: 5- Spontaneous improvement

The description is typical of acute sarcoidosis with erythema nodosum, polyarthropathy and hilar lymphadenopathy.

This has a good prognosis and usually resolves spontaneously over six to eight weeks.

[Q: 3399] OnExamination 2012 - Rheumatology

A 23-year-old female presents with left knee pain and a two month history of weight loss.

She has a good appetite but has had occasional episodes of diarrhoea over this time and tends to pass a loose motion at least twice daily. She is not taking any medication and there is a family history of hypothyroidism. She is a non-smoker and drinks modest quantities of alcohol.

Examination reveals a swollen, tender left knee joint with a small effusion.

Which is the most likely diagnosis?

- 1- Behcet's disease
- 2- Inflammatory bowel disease
- 3- Reactive arthritis
- 4- Thyrotoxicosis
- 5- Tuberculosis

Answer & Comments

Answer: 2- Inflammatory bowel disease

The description of weight loss, diarrhoea and a mono/oligo-arthropathy suggests a diagnosis of inflammatory bowel disease. (IBD).

IBD-associated arthropathy is considered a subtype of seronegative spondyloarthropathy. A variety of joint involvement has been described, from large joint pauciarticular arthropathy to a rheumatoid pattern polyarthropathy.

Peripheral arthritis is generally non-erosive and the oligoarticular variant particularly may correlate with intestinal disease activity.

Axial arthritis may include inflammatory back pain, sacroilitis, or ankylosing spondylitis and is less likely to correlate with gastrointestinal symptoms. Whilst there have been genetic factors identified, the mechanisms surrounding the development of arthritis in

IBD remain unclear. Treatment of the gastrointestinal disease is not always sufficient for control of arthritis, and biologic agents may be indicated.

Behcet's disease is a chronic inflammatory multisystem disorder characterised by recurrent oral and genital aphthosis and ocular involvement. Whilst arthropathy is fairly common, disturbance in bowel habit would not be expected. It is mainly present along the ancient Silk Road, from the Mediterranean to East Asia.

Reactive arthritis, formally known as Reiter's syndrome, is an autoimmune condition that develops in response to an infection. Classically this is described as a triad of urethritis, conjunctivitis and arthritis. Precipitating infections include gastrointestinal organisms such as Salmonella and genitourinary infections, especially Chlamydia.

Diarrhoea, if present, is typically more acute than is described in this scenario.

Whilst thyrotoxicosis can cause diarrhoea and arthralgia, a monoarthritis is unusual.

Tuberculous arthritis is now very rare in Europe, but can present in the spine, hip or knee. Infection is either from haematogenous spread (from lungs or intestine) or local spread (from a tuberculous focus in a neighbouring bone).

[Q: 3400] OnExamination 2012 - Rheumatology

A 64-year-old woman with a history of rheumatoid arthritis comes to the clinic for review.

She is taking weekly methotrexate to control her rheumatoid and is concerned as she has had two episodes of pneumonia over the past nine months.

On examination her BP is 122/72 mmHg, pulse is 75 and regular. There are occasional

crackles on auscultation of the chest, and evidence of active rheumatoid on examination of the small joints of the hands.

Investigations show:

Haemoglobin 11.4 g/dl(11.5-16.0)

White cell count $8.8 \times 10^9/L$ (4-11)

Platelets $182 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 118 micromol/l (79-118)

CXR - Nodular changes, unchanged over the past two years.

Which of the following is the most appropriate management with respect to her chest disease?

- 1- Add infliximab
- 2- Add low dose prednisolone
- 3- Decrease methotrexate dose
- 4- Increase methotrexate dose
- 5- Observation

Answer & Comments

Answer: 5- Observation

Rheumatoid nodules are commonly associated with the disease. They may occasionally be associated with increased risk of respiratory tract infection. Given the appearance on chest x ray has not changed over the past two years, no intervention is required.

An increase or a decrease in antirheumatoid medication is not necessarily indicated by the presence or absence of rheumatoid nodules. They are typically benign but can lead to pleural effusion, pneumothorax, haemoptysis, secondary infection, and bronchopulmonary fistula.

[Q: 3401] OnExamination 2012 -
Rheumatology

A 66-year-old man has a painful, swollen right knee and difficulty in walking which he has had for three days.

He had two self-limiting episodes of severe pain and swelling in the right big toe in the last year.

A knee aspirate shows no organisms on Gram stain, plenty of leucocytes, and negatively birefringent crystals on polarised light microscopy. Recent blood tests show a normal renal function, and a raised serum urate 452 $\mu\text{mol/l}$ (210-415).

Once the acute attack of gout has subsided, which of the following is the most appropriate drug in his long term management?

- 1- Allopurinol
- 2- Corticosteroids
- 3- Dietary advice
- 4- Febuxostat
- 5- Ibuprofen

Answer & Comments

Answer: 1- Allopurinol

Gout is the most prevalent form of inflammatory arthropathy. It is caused by the deposition of monosodium urate crystals with resultant inflammation in the involved joint.

Allopurinol is indicated in those with

More than two episodes of acute gout in a year

Tophaceous gout

Uric acid stones or

Renal insufficiency.

Starting treatment with allopurinol leads to changes in serum uric acid levels, which can mobilise intra-articular urate crystals, thereby triggering episodes of acute gout. In order to

prevent these attacks of gout, patients starting allopurinol (or other urate lowering therapy) should be co-prescribed colchicine 500 microgram bd for six months.

If there are contraindications to colchicine, or if it is not well tolerated, they should be commenced on NSAIDs/COX 2 inhibitors for a period of six weeks. The duration of treatment with NSAIDs/COX 2 inhibitors is shorter due to a higher risk of side effects than with colchicine. However, individual patients may require a longer course of treatment.

Febuxostat is a non-purine selective inhibitor of xanthine oxidase. It is recommended in cases of allopurinol hypersensitivity or intolerance.

Oral, intramuscular or intra-articular corticosteroids are effective in the control of acute gout. Prolonged corticosteroid use has significant side effects and is not indicated in the long term management of gout.

Similarly, ibuprofen may be used to treat acute gout, but has no role in the long term management of gout.

[Q: 3402] OnExamination 2012 -
Rheumatology

A 29-year-old woman with a history of SLE gives birth to her first child. She has suffered two previous miscarriages and has been managed with low molecular weight heparin injections during her pregnancy.

The labour is uneventful, but the midwives notice that the child has an erythematous rash. He is also bradycardic with a pulse of 75.

Which of the following antibodies is most likely to be linked to the illness in the baby?

- 1- Anti-LKM
- 2- Anti-Ro/SSA
- 3- Anti-smooth muscle
- 4- c-ANCA

5- Rheumatoid factor

Answer & Comments

Answer: 2- Anti-Ro/SSA

Neonatal lupus is an uncommon condition associated with the transplacental passage of maternal anti-Ro and/or anti-La autoantibodies.

Findings may include

Cutaneous lupus lesions

Third-degree heart block

Cardiomyopathy

Hepatobiliary disease and

Cytopenias.

Typically only one organ is affected in each infant.

The most severe manifestation is the heart block, which usually begins during the second trimester of pregnancy. It is rare, occurring in only 2% of mothers with anti-Ro or anti-La antibodies. Once established this is permanent, unlike the other manifestations which are generally transient.

The rash is most frequently seen around the eyes, but also occurs in other parts of the body.

Asymptomatic elevation of liver function tests is seen in 10-25% of cases.

Overall, non-cardiac involvement is more common than cardiac.

A significant number of babies with neonatal lupus are born to mothers who are not known to have systemic lupus erythematosus.

Anti-LKM and anti-smooth muscle antibodies are associated with autoimmune hepatitis.

c-ANCA is highly specific for Wegener's granulomatosis.

Rheumatoid factor is non-specific, but is seen at increased frequency in patients with rheumatoid arthritis.

Reference:

The clinical spectrum of neonatal lupus. Lee LA. Arch Dermatol Res. 2009 Jan;301(1):107-110

Cutaneous lupus in infancy and childhood. Lee LA. Lupus. 2010 Aug;19(9):1112-1117

Non-cardiac manifestations of neonatal lupus erythematosus. Silvermann E and Jaeggi E. Scand J Immunol. 2010 Sep;72(3):223-225

Arrhythmias presenting in neonatal lupus. Brucato A et al. Scand J Immunol. 2010 Sep;72(3):198-204

[Q: 3403] OnExamination 2012 - Rheumatology

A 32-year-old woman is referred from her general practice following a presentation with shortness of breath, myalgia, arthralgia and a skin rash.

Which of the following antibodies when found in this patient is most specific for systemic lupus erythematosus (SLE)?

1- ANA

2- Anti-Ro

3- Anti-Sm

4- cANCA

5- Rheumatoid factor

Answer & Comments

Answer: 3- Anti-Sm

The presence of anti-Sm antibodies is more specific for SLE than the other options.

ANA is positive in around 95% of patients with SLE but also occur in juvenile inflammatory arthritis, chronic active hepatitis and Sjogren's syndrome.

cANCA is present in Wegener's granulomatosis and pANCA is elevated in microscopic polyangiitis - another type of vasculitis.

Rheumatoid factor is found in several autoimmune conditions including rheumatoid arthritis, Felty's syndrome, systemic sclerosis and Sjogren's syndrome.

Anti-Ro is seen in SLE and in overlap syndromes with Sjogren's disease.

[Q: 3404] OnExamination 2012 - Rheumatology

A 48-year-old female with rheumatoid arthritis has the following full blood count results:

Haemoglobin 11.4 g/dL (11.5-16.5)

Platelets $470 \times 10^9/L$ (150-400)

White cell count $9.0 \times 10^9/L$ (4-11)

MCV 102 fL(80-96)

Which drug is she likely to be taking?

- 1- Ciclosporin
- 2- Hydroxychloroquine
- 3- Leflunomide
- 4- Methotrexate
- 5- Myocrisin

Answer & Comments

Answer: 4- Methotrexate

Leflunomide is associated rarely with anaemia, thrombocytopenia and eosinophilia.

Ciclosporin may be associated with a mild anaemia.

Methotrexate may be associated with haematopoietic suppression, leading to profound and sometimes sudden leucopenia and thrombocytopenia.

Methotrexate may lead to macrocytosis as a result of B12 or folate deficiency.

Myocrisin may also rarely lead to blood disorders, pancytopenia and leucopenia.

The elevated platelet count here probably relates to the rheumatoid arthritis itself.

[Q: 3405] OnExamination 2012 - Rheumatology

A 70-year-old female who has a history of chronic anxiety presents with a three day history of severe left temporal headache radiating from the eye to the scalp. She had also experienced discomfort during eating.

Which one of the following drugs should be given to this patient while awaiting the results of diagnostic tests?

- 1- Aciclovir
- 2- Carbamazepine
- 3- Diclofenac
- 4- Prednisolone
- 5- Sumatriptan

Answer & Comments

Answer: 4- Prednisolone

The features described here are classical for giant cell arteritis (GCA).

GCA affects large and medium sized arteries, with a predilection for the external carotid, ciliary and retinal arteries. Endovascular damage and cytokine-mediated inflammation causes local ischaemia. There is considerable overlap with polymyalgia rheumatica, and symptoms of both should be sought. Twenty per cent of patients develop loss of vision, which can be prevented with timely recognition and treatment.

The classically described jaw claudication occurs in a minority of cases, but does indicate a high risk of ischaemic complications.

The typical presentation of GCA is a temporal headache, with myalgia, malaise and fever. Erythrocyte sedimentation rate (ESR) and C reactive protein (CRP) are usually raised.

Once the diagnosis is suspected, high dose corticosteroids should be given. If visual symptoms are present, intravenous methylprednisolone should be given. Once symptoms and laboratory abnormalities resolve, the dose of corticosteroid can be reduced and usually stopped within two years.

A differential diagnosis is trigeminal neuralgia, although this tends to present with paroxysms of pain which last for thirty seconds to two minutes.

Carbamazepine is the first-line treatment. However, due to the threat to a patient's sight it is most appropriate to treat first for GCA in the above scenario.

Aciclovir could be used to treat ophthalmic shingles, however in this scenario you would expect characteristic lesions in addition to pain.

Diclofenac is a non-steroidal anti-inflammatory drug which is indicated in the management of simple headache.

Serotonin is a 5-HT₁ agonist which is used for the treatment of migraines and cluster headaches. It would be unusual for these to present for the first time in a 70-year-old patient, and it would be unusual for the attacks to last as long as described above.

[Q: 3406] OnExamination 2012 - Rheumatology

A female presents with headache, lethargy and weight loss.

Which of the following would make the diagnosis of giant cell arteritis (GCA) unlikely?

- 1- A normal ESR
- 2- Bilateral headache
- 3- Non-tender temporal arteries
- 4- Papilloedema without visual loss
- 5- The patient is 50-years-old

Answer & Comments

Answer: 4- Papilloedema without visual loss

Patients are usually elderly with a typical age of 70 but not exclusively so.

The temporal arteries are usually tender but they may be non-tender.

Similarly there is usually a unilateral headache but often presents as bilateral headache.

Erythrocyte sedimentation rate (ESR) is typically elevated but a normal ESR is well recognised.

However, papilloedema without visual loss would suggest raised intracranial pressure.

One would expect visual loss with anterior ischaemic optic neuropathy in GCA.

[Q: 3407] OnExamination 2012 - Rheumatology

An 81-year-old female presents with bilaterally painful knees. There was no history of gastrointestinal diseases. On examination she had crepitus but had a full range of movement of both knees.

Which one of the following is the most appropriate initial treatment for her painful knees?

- 1- Celecoxib
- 2- Dihydrocodeine
- 3- Naproxen
- 4- Paracetamol
- 5- Topical diclofenac

Answer & Comments

Answer: 4- Paracetamol

This woman has osteoarthritis (OA) of the knees.

The principal goal of systemic therapy is to provide the most effective pain relief with the

least associated toxicity. Paracetamol is the initial therapy recommended for the treatment of OA of the hip and knee. Studies have shown that the short term and long term efficacy of paracetamol is comparable with that of ibuprofen and naproxen in people with knee osteoarthritis.

Specific COX-2 inhibitors such as celecoxib have clinical benefit similar to that of traditional non-steroidal anti-inflammatory drugs (NSAIDs), but less gastrointestinal (GI) toxicity although issues remain regarding their cardiovascular risk. They may be used in patients with GI intolerance of traditional NSAIDs.

[Q: 3408] OnExamination 2012 - Rheumatology

A 45-year-old woman notices that she develops tingling and numbness over the palmar surface of her thumb, index, and middle fingers after several hours at her computer workstation doing word processing. Pain in the same area often occurs at night as well.

Which of the following pathologic findings most likely accounts for her symptoms?

- 1- Gout
- 2- Hypertrophic osteoarthropathy
- 3- Entrapment neuropathy
- 4- Rheumatoid arthritis
- 5- Toxic peripheral neuropathy

Answer & Comments

Answer: 3- Entrapment neuropathy

Carpal tunnel syndrome is one of the most common entrapment neuropathies, and is a recognised occupational disease. The carpal tunnel is an anatomical compartment bounded on three sides by the carpal bones, and the transverse carpal ligament on the palmar side. Intermittent or sustained high pressure within this compartment produces

ischaemia of the median nerve, resulting in the classical symptoms of paraesthesia and pain. If allowed to progress, weakness and wasting develop which eventually become irreversible.

Nerve conduction studies are an important diagnostic test, and are the best predictor of symptom severity and functional status. Treatment depends on severity, and includes splinting, corticosteroid interventions or surgical decompression. In the future pulsed radio frequency may be used.

Gout is caused by the deposition of monosodium urate crystals within a joint, leading to excruciating pain and swelling. It is not a common cause of the symptoms described above.

Hypertrophic osteoarthropathy may occur secondary to primary lung carcinoma. It presents with clubbing, arthralgia, arthritis and periostosis of the tubular bones. Pain is severe and is present throughout the day.

Rheumatoid arthritis is a possibility in women of this age group, but more commonly presents with swelling and pain of the small joints of the hand.

Toxic neuropathy presents with weakness, sensory loss and reduced reflexes secondary to diffuse nerve damage. This can be caused by a variety of agents but is much less common than carpal tunnel syndrome, making it a less likely answer in this case.

[Q: 3409] OnExamination 2012 - Rheumatology

A 62-year-old man has back pain.

An FBC reveals the following:

WBC $3.7 \times 10^9/L$ (4-11)

Haemoglobin 10.3 g/dl (14-18)

MCV 85 fl (80-100)

Platelets $110 \times 10^9/L$ (150-400)

His total serum protein is 85 g/l with an albumin of 41 g/l. A chest x ray shows no abnormalities of heart or lung fields, but there are several lucencies in the vertebral bodies. You perform a sternal bone marrow aspirate and get a dark red jelly-like material in the syringe.

The smear of the aspirate is most likely to show which of the following cell types as a prominent feature?

- 1- Fibroblasts
- 2- Giant cells
- 3- Metastatic renal cell carcinoma cells
- 4- Osteoblasts
- 5- Plasma cells

Answer & Comments

Answer: 5- Plasma cells

The patient has multiple myeloma. The bone marrow needle was in a lytic lesion filled with plasma cells. His serum globulin is high from a monoclonal gammopathy.

Osteoblasts are most numerous in repair of bone, and callus is very firm.

Fibroblasts produce collagen and are more numerous with the gross appearance of firm, white scar tissue.

Giant cells may be seen in a variety of benign and malignant lesions of bone, but this does not explain the hypergammaglobulinaemia.

Osteolytic metastases of renal cell carcinoma could have the gross appearance described here, but would not account for hypergammaglobulinaemia.

[Q: 3410] OnExamination 2012 - Rheumatology

A 35-year-old woman who was two months postpartum presented with a four week history of joint pain, facial rash and fever.

Blood tests reveal an ESR of 40 mm/hour (0-20).

What is the most likely diagnosis?

- 1- Reactive arthritis
- 2- Rheumatoid arthritis
- 3- Sarcoidosis
- 4- Systemic lupus erythematosus (SLE)
- 5- Viral arthritis

Answer & Comments

Answer: 4- Systemic lupus erythematosus (SLE)

The triad of fever, arthralgia and rash in a woman of childbearing age should suggest the diagnosis of systemic lupus erythematosus (SLE).

SLE is a heterogenous multisystem autoimmune inflammatory disease, in which antinuclear antibodies occur. Its presentation and course are highly variable, ranging from indolent to fulminant. The diagnosis is based on the American College of Rheumatology (ACR) criteria. Management depends on disease severity.

Reactive arthritis is a post-infective autoimmune condition that is associated with gastrointestinal (Shigella, Salmonella, Campylobacter) and genitourinary infections (Chlamydia). Classically it presents with arthritis and conjunctivitis. There will be a recent history of gastroenteritis or urethritis.

Rheumatoid arthritis typically presents with a persistent symmetrical polyarthritis affecting the hands and feet. Extra-articular features such as fever and rash occur much less commonly than in SLE. Anti-CCP antibodies are highly specific and should be tested if the diagnosis is suspected.

Sarcoidosis is a multisystem inflammatory disease of unknown aetiology, characterised by the presence of non-caseating granulomas in affected tissue. Approximately 5% of cases

are asymptomatic and are detected on chest x ray.

Sarcoid commonly presents with a dry cough, with or without dyspnoea and systemic complaints.

Viral arthritis is a condition which is difficult to diagnose. It occurs during the viral prodrome, and is often accompanied by a rash. Most commonly patients present with symmetrical small joint involvement, although the exact pattern depends on the causative virus. Viruses commonly associated include parvovirus B19, hepatitis A, B and C, rubella and HIV.

Whilst the fever, rash and joint pain in the above scenario would be consistent with viral arthritis, symptoms would have typically resolved over a four week period.

[Q: 3411] OnExamination 2012 - Rheumatology

A 38-year-old woman from Pakistan presents with a six week history of non-productive cough, subjective fever, chills and progressively worsening shortness of breath.

She reports that recently she has been able to walk for only five to 10 minutes before having to stop and rest for breath. She has lost 2 kg over this period.

There is no recent travel history or guests visiting from endemic regions.

She has a 10 year diagnosis of rheumatoid arthritis for which she was commenced on etanercept six months ago.

Clinical examination demonstrated: temperature 38.0°C, pulse 100 regular, normal heart sounds, respiratory rate 18, mild mid zone inspiratory crepitations, SaO₂ 98% (pre-exertion), 89% (post exertion).

Basic bloods show;

Hb 10.7g/dL(11.5-16.5)

MCV 88fL(80 - 96)

WCC $4.9 \times 10^9/L$ (4 - 11)

Westergren ESR 44/hr(0 - 20)

CRP 34mg/L(<10)

Chest radiography demonstrates diffuse bilateral infiltrates.

Which test is most likely to be diagnostic?

- 1- Aspergillus precipitin
- 2- Bronchoalveolar lavage
- 3- High resolution CT
- 4- Mycoplasma serology
- 5- QuantiFERON

Answer & Comments

Answer: 2- Bronchoalveolar lavage

Learning points:

Potential complications of anti-TNF use in rheumatoid arthritis

Clinical presentation of Pneumocystis jiroveci (PCP).

This patient has developed Pneumocystis jiroveci (formerly Pneumocystis carinii) pneumonia after commencing anti-TNF therapy, a known risk factor.

The temporal relationship, dry cough, fever, weight loss and inducible post exertional hypoxia should point you towards this diagnosis.

Anti-TNF therapy also predisposes mycobacterial infection and this must be excluded before commencing treatment.

Her radiograph and a clinical history of 2 kg weight loss in two months (insignificant value) are not consistent with this diagnosis.

[Q: 3412] OnExamination 2012 - Rheumatology

A 72-year-old man presents with a three day history of acute onset, progressively worsening knee pain which began 24 hours

after returning from a walking holiday in the New Forest. There is associated knee joint stiffness in the morning lasting approximately 20 minutes. He has an intermittent subjective fever.

He is currently partially weight bearing and reports particular difficulty ascending the stairs at home. His temperature is 37.2°C, pulse 88, blood pressure 128/90 mmHg. The left knee is swollen, tender and normothermic with crepitus present during a markedly reduced active range of motion.

Initial investigations demonstrated the following;

FBC normal

Westergren ESR 38mm/hr(0 - 30)

CRP <5mg/L(< 10)

Rheumatoid factor titre 1:80(>1:40)

Synovial fluid aspirate WCC 1800/mm³ (<2000)

Which one of the following is the most likely diagnosis?

- 1- *Borrelia burgdorferi* monoarticular synovitis
- 2- Calcium pyrophosphate arthropathy
- 3- Patellofemoral osteoarthritis
- 4- Prepatellar bursitis
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 3- Patellofemoral osteoarthritis

Learning points:

Clinical criteria for diagnosing knee osteoarthritis (OA)

Clinical presentation of OA

Common differentials for OA

Basic investigations and work up of monoarticular pain.

This 72-year-old man presents with a classical history for patellofemoral osteoarthritis (OA).

His age (greater than 45 years)

Morning stiffness lasting less than 30 minutes

Functional limitation and

Joint crepitus on active motion

fulfill the clinical criteria for diagnosis.

Joint crepitus does not occur with prepatellar bursitis.

His inflammatory markers are normal, militating against rheumatoid arthritis.

The upper limit for synovial fluid WCC in OA is 2000/mm³. White cells higher than this may suggest an inflammatory or septic arthritis, depending on the clinical context.

His weakly positive rheumatoid factor (titre should be greater than 1:40) is likely a product of his age.

The minimum incubation period for Lyme disease is three days, and the diagnosis is much less likely in a patient of this age where osteoarthritis is highly prevalent

There is no mention of crystals on synovial fluid examination to suggest pseudogout, although this can complicate osteoarthritis.

[Q: 3413] OnExamination 2012 - Rheumatology

A 25-year-old lady presents with rapidly worsening Raynaud's phenomenon, and skin tightness.

On examination, there is sclerodactyly, skin thickening to the shoulders, and bi-basal crepitations. Muscle strength is normal.

Recent blood tests are:

Hb 12.1g/dl(11.5 - 16.5 g/dL)

WBC 7.8 x 10⁹/L (4 - 11 x 10⁹/L)

Neutrophils 70%(40-75%)

Platelet $270 \times 10^9/\mu\text{l}$ ($150 - 400 \times 10^9/\text{L}$)
 ESR 36 mm/hr ($0 - 20 \text{ mm}/1\text{st hr}$)
 Anti-nuclear anti-body positive (1:6400)
 (Negative at 1:20 Dil)
 Anti-centromere antibody negative (Negative
 at 1:40 Dil)
 Anti-Scl70 antibody positive (1:640)
 (Negative)
 Anti-U1RNP negative (Negative)
 Anti-Ro/La antibody negative (Negative)
 Urea, electrolytes and creatinine Normal

What is the diagnosis?

- 1- Dermatomyositis
- 2- Diffuse cutaneous systemic sclerosis
- 3- Limited cutaneous systemic sclerosis
- 4- Mixed connective tissue disease
- 5- Sjogren's syndrome

Answer & Comments

Answer: 2- Diffuse cutaneous systemic sclerosis

This patient has diffuse cutaneous systemic sclerosis with pulmonary fibrosis.

Diffuse cutaneous systemic sclerosis is characterised by

Skin thickening proximal to the knees and elbows

Anti-Scl70 antibodies

Pulmonary fibrosis, and rarely by

Scleroderma renal crisis.

Limited cutaneous systemic sclerosis is characterised by

Skin thickening distal to knees, and elbows (although face may be involved in either type)

Anti-centromere antibodies, and

A tendency to develop pulmonary hypertension.

She does not have any muscle weakness, or rash making dermatomyositis unlikely. Dermatomyositis associates with Gottron's papules on extensor surface of hands, and a periorbital heliotrope rash.

The co-existence of myositis, arthritis, and scleroderma in those with anti-U1 RNP antibodies suggests mixed connective tissue disease. This is clearly not the case here.

[Q: 3414] OnExamination 2012 - Rheumatology

A 76-year-old man presents with a painful, swollen right knee and difficulty in walking for three days.

On examination, his temperature is 36.8 C. The right knee is red, swollen, warm and tender and has restricted movement.

The knee aspirate shows no organisms on Gram stain, 200 leucocytes/mm³, and weakly positively birefringent crystals on polarised light microscopy.

The results of recent blood tests are:

Hb 12.3 g/dl ($13.0 - 18.0 \text{ g/dL}$)

WBC $14.3 \times 10^9/\text{L}$ ($4 - 11 \times 10^9/\text{L}$)

Neutrophils 88% ($40-75\%$)

Platelet $340 \times 10^9/\text{L}$ ($150 - 400 \times 10^9/\text{L}$)

Urea, electrolytes and creatinine: Normal

ESR 79 mm/hr ($0 - 20 \text{ mm}/1\text{st hr}$)

Urate 321 $\mu\text{mol/l}$ ($210-415 \mu\text{mol/l}$)

What is the most likely diagnosis?

- 1- Gout
- 2- Osteoarthritis
- 3- Pseudogout
- 4- Reactive arthritis
- 5- Septic arthritis

Answer & Comments

Answer: 3- Pseudogout

This presentation could be consistent with a number of diagnoses. However, the presence of positively birefringent crystals make pseudogout (calcium pyrophosphate arthropathy) the most likely diagnosis. It is critical to exclude septic arthritis, as it is potentially rapidly destructive, but the negative gram stain and low synovial fluid white cell count make this less likely.

Classically pseudogout presents with a rapid onset of inflammatory symptoms and signs. Risk factors include age, osteoarthritis and metabolic disturbance (e.g. primary hyperparathyroidism, haemochromatosis). Management of acute episodes include cool packs, rest, joint aspiration and steroid injection. Prophylaxis is typically with oral NSAIDs and/or low-dose colchicine. Oral corticosteroids, methotrexate or hydroxychloroquine can be used in resistant disease. Asymptomatic crystal deposition does not need treatment. The differential does include gout but isolated monoarthritis of the knee is less common than with pseudogout. Distinguishing between the two depends on analysis of the crystals with calcium pyrophosphate crystals demonstrating no or positive birefringence and urate crystals demonstrating a negative birefringence under polarising light.

The white cell count in septic arthritis is typically more than 2000/mm³, with more than 75% polymorphonuclear leucocytes. Gram stain may be positive.

Osteoarthritis of the knee usually presents as a more chronic mechanical joint pain.

Reactive arthritis is more common in younger patients, and there is a typically a history of infection (usually gastroenterological or sexually-transmitted) which predates the onset of joint symptoms.

[Q: 3415] OnExamination 2012 - Rheumatology

A 37-year-old lady with well controlled asthma since teenage presents with a six week history of gradually worsening asthma, sinusitis, weight loss, and fatigue.

On examination, there is scattered wheeze bilaterally, and there is a non-blanching petechial rash on the shin. Muscle strength is normal.

Recent blood tests show:

Hb 11.1gm/dl(11.5 - 16.5 g/dL)

WBC 14.8 x 10⁹/L (4 - 11 x 10⁹/L)

Neutrophils 60%(40-75%)

Lymphocytes 10%(20-45%)

Eosinophils 30%(1-6%)

Platelet 270 x 10⁹/L (150 - 400 x 10⁹/L)

ESR 86 mm/hr(0 - 20 mm/1st hr)

CRP 143 mg/L(< 10 mg/L)

Anti-myeloperoxidase antibody Positive

pANCA Positive

cANCA negative

Urea, electrolytes & creatinine normal

What is the diagnosis?

- 1- Allergic bronchopulmonary aspergillosis
- 2- Churg-Strauss syndrome
- 3- Eosinophilic pneumonia
- 4- Hypersensitivity pneumonitis
- 5- Wegener's granulomatosis

Answer & Comments

Answer: 2- Churg-Strauss syndrome

Churg-Strauss syndrome (CSS) is a rare form of small-vessel vasculitis, characterised by asthma, allergic rhinitis and prominent peripheral blood eosinophilia. All of these are present in the history and should lead you to the diagnosis of Churg Strauss.

The most commonly involved organ is the lung, followed by the skin. CSS, however, can affect any organ system, including the cardiovascular, gastrointestinal, renal, and central nervous systems. The unifying feature of patients presenting with CSS is asthma. Vasculitis involving the peripheral nervous system is also a characteristic feature, and mononeuritis multiplex occurs in 75% of patients.

Vasculitis of extrapulmonary organs is largely responsible for the morbidity and mortality associated with CSS. 40-60% are associated with positive ANCA, usually pANCA/MPO.

ANCA are antineutrophil cytoplasmic antibodies. Several different staining patterns and antigen specificities are recognised. The cytoplasmic staining pattern, cANCA, and specificity for the PR3 antigen is most specific for Wegener's granulomatosis. Perinuclear staining, pANCA, and/or antibody to MPO are far less specific than cANCA and can be present in a range of inflammatory conditions such as microscopic polyangitis, Churg-Strauss syndrome and Goodpasture's syndrome. MPO and pANCA may also be present in SLE, rheumatoid arthritis, Sjogren syndrome and occasionally in chronic infections.

Intravenous glucocorticoid is used for initial therapy of acute multi-organ involvement in Churg-Strauss syndrome, followed by oral glucocorticoid therapy, often with azathioprine as a steroid-sparing agent. Loss of vision is rare but can occur and must be treated aggressively.

Allergic bronchopulmonary aspergillosis is a hypersensitivity reaction to *Aspergillus*. Its clinical presentation varies from corticosteroid-dependent asthma to diffuse bronchiectasis with fibrosis. Visual loss is not an associated feature.

Wegener's granulomatosis is a multi-organ autoimmune disease, which can be fatal. The

classical triad consists of necrotising granulomatous inflammation of the respiratory tract, glomerulonephritis and a small-vessel vasculitis. A prolonged history of epistaxis or sinusitis is commonly found in Wegener's granulomatosis, which in some patients is also associated with an eosinophilia.

Hypereosinophilic syndrome is characterised by a peripheral blood eosinophil count of >1.5 for more than 6 months. Generalised symptoms are fatigue, myalgia, fever, night sweats, diarrhoea and pruritis. Other symptoms depend on the organ involved: cardiac disease causes chest pain and dyspnoea, respiratory disease presents with a dry cough.

[Q: 3416] OnExamination 2012 - Rheumatology

A 67-year-old woman with polymyalgia rheumatica was commenced on prednisolone 15 mg/day, and had excellent therapeutic response.

The steroid dose has now been reduced to 10 mg/day, and the plan is to continue tapering the prednisolone dose by 1 mg/month, aiming to discontinue prednisolone in a year's time.

Which of the following is the best approach to osteoporosis prophylaxis for her?

- 1- Alendronic acid
- 2- Alendronic acid, and calcium carbonate + vitamin D
- 3- Calcium carbonate
- 4- Calcium carbonate + vitamin D
- 5- Check bone mineral density

Answer & Comments

Answer: 2- Alendronic acid, and calcium carbonate + vitamin D

Oral glucocorticoids are associated with significant increase in fracture risk from doses as low as 5 mg daily. Loss of bone mineral density is greatest in the first few months of glucocorticoid therapy, but fracture risk declines rapidly after stopping. There is an increased risk of fracture over and above the effect of low bone mineral density.

Patients older than 65 years are considered at high risk of osteoporotic fractures, as are those with a prior fragility fracture, and they should commence on bone protective therapy at the time of starting glucocorticoid therapy.

Measurement of bone density is not required before starting therapy. In patients younger than 65 years without risk factors, DEXA scan is recommended for assessment of fracture risk.

General measures to reduce bone loss include use of the lowest dose of glucocorticoids possible, and steroid-sparing agents. Dietary calcium should be increased and physical activity, with smoking and alcohol minimised. Daily intake 1,500 mg of calcium and 800U of vitamin D3 is recommended.

Bone protective therapy which can be used includes alendronate, alfacalcidol, calcitonin, calcitriol, cyclic etidronate and risedronate.

[Q: 3417] OnExamination 2012 - Rheumatology

An 84-year-old man presents with right upper arm pain which he has had for the last few months. The pain is worsening progressively, and wakes him up at night.

He is known to have Paget's disease involving lumbar spine and pelvis, and is on oral bisphosphonates for this. There is no history of injury.

On examination the shoulder movements are free, and normal.

What is the most likely cause of his arm pain?

- 1- Fracture
- 2- Osteoarthritis
- 3- Osteonecrosis
- 4- Osteosarcoma
- 5- Paget's disease

Answer & Comments

Answer: 4- Osteosarcoma

Osteosarcoma is the most likely cause of his arm pain.

Osteosarcoma occurs in 1% of patients with Paget's disease, and accounts for 30% of cases of late onset osteosarcoma.

Although Paget's disease is associated with pathological fracture at the affected site, this man is not known to have Paget's disease at the humerus - which is an uncommon site for Paget's disease anyway; and there is no history of injury.

Similarly, the speed of progression of symptoms, presence of night pain and normal joint movements precludes the diagnosis of osteoarthritis.

Osteonecrosis has been associated with intravenous bisphosphonates (for example, zoledronic acid), and although rare, occurs in cancer patients who may be treated with large doses of corticosteroids, or who are known to have bone metastases.

[Q: 3418] OnExamination 2012 - Rheumatology

A 80-year-old man presents with deteriorating lumbar and bilateral hip pains. He has recently been seen by his GP with symptoms of prostatism.

Investigations revealed:

Full blood count Normal

Corrected Calcium 2.3 mmol/l (2.2-2.6)

ESR 22 mm/1st hr(1-10)

Alkaline phosphatase 985 U/l (60-110)

Gamma-GT 33 U/l (<50)

Prostate specific antigen 6.6 pg/l (0-6)

What is the most likely cause of this man's pain?

- 1- Multiple myeloma
- 2- Osteomalacia
- 3- Paget's disease of the pelvis
- 4- Polymyalgia rheumatica (PMR)
- 5- Prostatic carcinoma with metastases

Answer & Comments

Answer: 3- Paget's disease of the pelvis

This elderly patient presenting with bone pains has elevated alkaline phosphatase with normal calcium concentrations suggesting a diagnosis of Paget's disease.

The slightly elevated PSA is in keeping with benign prostatic hypertrophy rather than prostatic malignancy where a PSA of above 10 would be expected in widespread disease.

The normal calcium and only slightly elevated erythrocyte sedimentation rate (ESR) argues against osteomalacia, myeloma and PMR.

Regarding Paget's disease:

Increased bone turnover gives disordered bone formation, abnormal remodelling and deformity

Typically affects elderly patients

Can be asymptomatic

Symptoms include deafness, bone pain, breathlessness due to high-output cardiac failure (rare) and nerve compression

Complications include pathological fractures and there is a small risk of developing osteosarcoma.

Treatment is with bisphosphonates and analgesia.

[Q: 3419] OnExamination 2012 - Rheumatology

A 55-year-old lady presents with swelling, increased sweating, persistent erythema, and increased pain sensitivity in her right hand, and forearm for the last few months.

She had a right Colles fracture four months ago, and has been discharged from orthopaedics with good fracture healing.

On examination, the affected limb is swollen, erythematous, sweaty and there is increased pain sensitivity on the affected side. Fine touch is perceived as painful. Recent blood tests have been normal.

What is the diagnosis?

- 1- Cellulitis
- 2- Complex regional pain syndrome type I
- 3- Complex regional pain syndrome type II
- 4- Deep vein thrombosis
- 5- Osteomyelitis

Answer & Comments

Answer: 2- Complex regional pain syndrome type I

This patient has complex regional pain syndrome (CRPS) which is a chronic pain condition that can affect any area of the body, but often affects an arm or a leg, and occurs after an injury or rarely after a sudden illness such as a heart attack or stroke.

The condition can sometimes appear without obvious injury to the affected limb.

CRPS has two forms:

CRPS I occurs in the absence of a preceding nerve injury

CRPS II is caused by an injury to the nerve.

The key symptom is pain that

Is intense and burning

Is disproportionate to the original injury

Is worse over time

Spreads beyond the site of injury and

Is associated with hyperalgesia, hyperpathia or allodynia on examination. These features do not occur in DVT, osteomyelitis, or cellulitis.

CRPS may have three stages (acute, dystrophic, and atrophic), with variable progression from one stage to another.

CRPS is a clinical diagnosis, and various imaging modalities show non-specific changes which support its diagnosis:

Plain radiographs may show soft tissue swelling, peri-articular osteoporosis, and rarely erosions

MRI may also show bone marrow oedema apart from these changes

99mTc bone scan shows hypervascularity in the acute phase, and hypovascularity in the atrophic phase.

In the atrophic phase, imaging may show contractures.

[Q: 3420] OnExamination 2012 - Rheumatology

A 52-year-old businessman presents to the emergency department complaining of worsening pain in his right big toe and knee.

He has recently been diagnosed by his GP with gout, and you can see from the computer that his urate at the time was 0.55 mmol/l (0.18-0.42). Current medication is 300 mg of allopurinol per day.

On examination he has severe pain and swelling over his right first MTP joint, consistent with gout.

What is the most appropriate management?

- 1- Add colchicine to his regime
- 2- Add naproxen to his regime
- 3- Decrease allopurinol to 100 mg

4- Decrease allopurinol to 200 mg

5- Stop allopurinol for a few days

Answer & Comments

Answer: 2- Add naproxen to his regime

Guidelines on the management of acute gout and advice on what to do with an acute attack of gout whilst on allopurinol exist in the summary of product characteristics (SPC) for the drug. These state that an acute flare whilst on allopurinol should not lead to cessation of the agent, but that it should be continued at the same dose, and a suitable non-steroidal anti-inflammatory agent added.

Colchicine is a reasonable alternative but is known to precipitate diarrhoea when an efficacious dose is reached, so is not normally the first line recommendation.

[Q: 3421] OnExamination 2012 - Rheumatology

A 72-year-old lady presents with pain and swelling of the left wrist.

Three weeks ago she received an intra-articular steroid injection into the wrist as treatment of chronic pain which was thought to be due to osteoarthritis.

On examination the joint is erythematous, swollen and tender.

Results reveal:

White cell count $12.5 \times 10^9/L$ ($4-11 \times 10^9$)

Rheumatoid factor 34 U/L (<20)

x Ray of wrist revealed a bony destruction of the joint and wrist aspiration revealed only a dry tap.

What is the most likely diagnosis?

- 1- Acute gout
- 2- Acute inflammatory reaction related to osteoarthritis
- 3- Acute rheumatoid arthritis

4- Pyrophosphate arthropathy

5- Septic arthritis

Answer & Comments

Answer: 5- Septic arthritis

Septic arthritis is a potential catastrophic complication of intra-articular steroid injection, although it is rare. In general there is wide variation in the precautions taken to avoid such a complication. Fluid should be aspirated for urgent Gram-stain and antibiotics started immediately (choice depends on local policy).

Gout presents with acute onset of pain, classically in the first metatarsophalangeal joint of the foot, due to monosodium urate crystal deposition. It is more common in men than women.

Pseudogout more commonly complicates osteoarthritis, and results from calcium pyrophosphate crystal deposition. The knee is affected more often than the wrist, and in the context of recent instrumentation it is critical septic arthritis is excluded.

A flare of osteoarthritis is a possibility but septic arthritis needs to be excluded before making this diagnosis.

In a lady of this age, with no other features and a known diagnosis of osteoarthritis, rheumatoid arthritis is unlikely. The positive rheumatoid factor is a red herring, it is mildly positive here and is found in 2.5% of the population and may be raised in association with malignancy, systemic lupus erythematosus and infection.

[Q: 3422] OnExamination 2012 - Rheumatology

A 52-year-old woman with type 2 diabetes presents with a two month history of painful hands and feet.

Investigations confirm a diagnosis of sero-positive erosive rheumatoid arthritis. She has some pain relief from non-steroidal anti-inflammatory agents. She currently takes metformin 500 mg tds and has good glycaemic control as reflected by a HbA1c of 6.7% (3.8-6.4).

Which of the following DMARDS would be most appropriate initial treatment of her early rheumatoid arthritis?

1- Ciclosporin

2- Etanercept

3- Hydroxychloroquine

4- IM gold

5- Methotrexate

Answer & Comments

Answer: 5- Methotrexate

Guidance recommends the use of disease modifying anti-rheumatic drugs (DMARDs) early in the treatment of rheumatoid arthritis, maintaining function and reducing progression of the disease (SIGN 2001). First line agents include methotrexate and sulfasalazine (SIGN 2000) and most subjects receive methotrexate.

Generally gold is considered more toxic than the former two and hydroxychloroquine is probably less effective.

Ciclosporin is again rather more toxic than either methotrexate or sulfasalazine, with nephrotoxicity and immunosuppression and is generally reserved for RHA with systemic features such as vasculitis.

The tumour necrosis factor (TNF) alpha antagonists, etanercept and infliximab, are generally reserved for individuals unresponsive to traditional DMARDs*.

Reference:

British Society for Rheumatology guidelines

[Q: 3423] OnExamination 2012 -
Rheumatology

A 55-year-old woman receiving 10 mg of methotrexate and 5 mg of folate* weekly presents with a sore right finger after cutting herself in the garden.

On examination she has a swollen erythematous right ring finger up to the proximal interphalangeal joint and you diagnose a cellulitis. You give her a prescription for erythromycin as she is allergic to penicillins. She has been receiving the methotrexate for just over one year with no problems and all routine blood monitoring has been normal.

Whilst monitoring the response of the infection to treatment, what is the most appropriate strategy regarding her methotrexate therapy?

- 1- Continue methotrexate and folate unchanged.
- 2- Continue methotrexate unchanged and increase folate supplements to 10 mg daily.
- 3- Reduce dose of methotrexate to 5 mg weekly
- 4- Stop methotrexate only if full blood count reveals a neutropenia.
- 5- Stop methotrexate until the infection has resolved.

Answer & Comments

Answer: 5- Stop methotrexate until the infection has resolved.

In the circumstances of infection one should consider temporarily stopping methotrexate as it is an immunosuppressant.

Any infection should be treated as usual and the response to treatment monitored. Once the infection has been successfully treated methotrexate can be reinstated. However, if the patient has recurrent serious infections

while taking methotrexate its continued long term use should be discussed with the patient's rheumatologist.

*Some local variations may exist regarding dose and frequency of folate therapy. Please be aware of your local guidelines.

[Q: 3424] OnExamination 2012 -
Rheumatology

A 36-year-old man attends clinic for advice.

He is currently taking methotrexate 7.5 mg weekly. His wife is fit and well, with no past medical history of note and not taking any medication apart from the oral contraceptive pill.

They are keen to start a family and want to know about continued contraception and whether there is a need to stop methotrexate.

Which of the following would you advise?

- 1- They can discontinue with contraception now and the husband can continue with the methotrexate
- 2- They can discontinue with contraception now but the husband needs to stop taking methotrexate
- 3- They should continue with adequate contraception for at least four weeks after the husband stops the methotrexate
- 4- They should continue with adequate contraception for at least three months after the husband stops the methotrexate
- 5- They should continue with adequate contraception for at least one year after the husband stops the methotrexate

Answer & Comments

Answer: 4- They should continue with adequate contraception for at least three months after the husband stops the methotrexate

Methotrexate is teratogenic and, according to the British National Formulary (BNF), the manufacturers advise effective contraception during and for at least three months after stopping methotrexate.

Fertility may be reduced during treatment, but this usually reverses upon stopping. This advice applies to both females and males who are taking methotrexate.

The National Patient Safety Agency (NPSA) state on their patient held record that "It is recommended that men wait six months after finishing their treatment, before trying to father a child as sperm can be affected".

[Q: 3425] OnExamination 2012 - Rheumatology

A 35-year-old woman presents with malaise, thirst and increasing nocturia over the last month.

Six months ago she attended the Emergency department with an episode of renal colic. One month previously her GP had noted an eruptive, painful, erythematous rash on the anterior shins, which was self-limiting.

What is the likely cause of her symptoms?

- 1- Hypercalcaemia
- 2- Hyperglycaemia
- 3- Hypocalcaemia
- 4- Hypokalaemia
- 5- Hyperoxaluria

Answer & Comments

Answer: 1- Hypercalcaemia

The most likely diagnosis in this case is sarcoidosis.

Sarcoidosis is a multisystem granulomatous disorder. It is relatively uncommon in the United Kingdom as a whole, but is more prevalent and more severe in Afro-Caribbean

populations. Onset of symptoms is typically in adults around 20-40-years-old.

Features of sarcoidosis include:

Bilateral hilar lymphadenopathy

Hypercalcaemia, which may be sensitive to steroids

Erythema nodosum

Neurological sequelae including neuropathy and Bell's palsy

Cardiomyopathy

Eye inflammation: uveitis and conjunctivitis

Hepatosplenomegaly.

Hypercalcaemia has a varied presentation.

At levels less than 2.8mmol/L polyuria, polydipsia, dyspepsia, depression and mild cognitive impairment predominate. At levels up to 3.5mmol/L patients present with muscle weakness, constipation, anorexia, nausea and fatigue. Above this level, patients develop vomiting, dehydration, cardiac arrhythmias, coma and pancreatitis.

Hyperglycaemia can cause thirst, nocturia and malaise but is not commonly associated with renal colic or erythema nodosum.

Hypocalcaemia leads to paraesthesia, tetany, carpopedal spasm and muscle cramps.

Hypokalaemia is generally asymptomatic, but severe deficiency can cause muscle weakness, paraesthesia and tetany.

Hyperoxaluria can be either primary or secondary, and is normally asymptomatic until nephrolithiasis develops.

[Q: 3426] OnExamination 2012 - Rheumatology

Which of the following best describes the mode of action of alendronate?

- 1- Inhibits osteoclast activity

- 2- Promotes bone matrix calcification
- 3- Promotes collagen synthesis
- 4- Promotes renal absorption of calcium
- 5- Stimulates osteoblast activity

Answer & Comments

Answer: 1- Inhibits osteoclast activity

Simple bisphosphonates such as clodronate and etidronate inhibit bone resorption through induction of osteoclast apoptosis.

Clodronate, and perhaps etidronate, triggers apoptosis by generating a toxic analogue of adenosine triphosphate which then targets the mitochondria.

For nitrogen-containing bisphosphonates the direct intracellular target is the enzyme farnesyl diphosphate synthase in the cholesterol biosynthetic pathway. Its inhibition suppresses a process called protein geranylgeranylation which is essential for the basic cellular processes required for osteoclastic bone resorption.

Although nitrogen-containing bisphosphonates can induce osteoclast apoptosis this is not necessary for their inhibition of bone resorption.

[Q: 3427] OnExamination 2012 - Rheumatology

A 39-year-old female presents with weakness, diplopia and fatigue.

She had recently been diagnosed with rheumatoid arthritis.

On examination there is bilateral ptosis and weakness of abduction of both eyes and mild proximal weakness of the arms and legs but normal reflexes and sensation.

What is the most likely diagnosis?

- 1- Guillain-Barré syndrome
- 2- Mononeuritis multiplex

- 3- Multiple sclerosis
- 4- Myasthenia gravis
- 5- Polymyositis

Answer & Comments

Answer: 4- Myasthenia gravis

The most likely diagnosis is myasthenia gravis.

There is an association between myasthenia gravis and thyroid disease, pernicious anaemia, systemic lupus erythematosus and rheumatoid arthritis. The condition is more common in women with a peak incidence around the age of 30. It is characterised by weakness and fatigability of the proximal limb muscles, ocular and bulbar muscles.

Seventy five per cent of patients initially complain of ocular disturbance, mainly ptosis and diplopia. Reflexes are initially preserved but may be fatigable. In Guillain-Barre syndrome there is a post-infective weakness and numbness in the distal limbs which ascends over days and weeks.

Multiple sclerosis can produce a variety of neurological symptoms. Common ophthalmic presentations include optic neuritis and internuclear ophthalmoplegia.

Mononeuritis multiplex describes an asymmetric asynchronous sensory and motor peripheral neuropathy, involving at least two separate nerve areas. It can be caused by a number of different disorders, including diabetes, vasculitis, Lyme disease and sarcoidosis.

Polymyositis classically presents with relatively painless progressive proximal muscle weakness. Dysphagia is common but the ocular muscles are very rarely involved unlike myasthenia gravis where this is a predominant feature.

[Q: 3428] OnExamination 2012 - Rheumatology

A 72-year-old man presents with an acutely painful right knee.

On examination, he has a temperature of 37°C with a hot, swollen right knee.

Of relevance amongst his investigations, is a white cell count of $12.6 \times 10^9/L$ ($4-11 \times 10^9$) and a knee radiograph which shows reduced joint space and calcification of the articular cartilage.

Culture of aspirated fluid reveals no growth.

What is the most likely diagnosis?

- 1- Gout
- 2- Pseudogout
- 3- Psoriatic monoarthropathy
- 4- Rheumatoid arthritis
- 5- Septic arthritis

Answer & Comments

Answer: 2- Pseudogout

This is a typical presentation of pseudogout / (calcium pyrophosphate arthropathy) with evidence of osteoarthritis, calcification of the articular cartilage and no growth on synovial culture. Classically there is rapid onset inflammatory symptoms and signs. Risk factors include age, osteoarthritis and metabolic disturbance (e.g. primary hyperparathyroidism, haemochromatosis). Management of acute episodes include cool packs, rest, joint aspiration and steroid injection. Prophylaxis is typically with oral NSAIDs and/or low-dose colchicine. Oral corticosteroids, methotrexate or hydroxychloroquine can be used in resistant disease. Asymptomatic crystal deposition does not need treatment.

The differential does include gout but isolated monoarthritis of the knee is less common than with pseudogout. Distinguishing between the two depends on analysis of the

crystals with calcium pyrophosphate crystals demonstrating no or a positive birefringence and urate crystals demonstrating a negative birefringence under polarising light.

Distinguishing between the two depends on analysis of the crystals with CPP crystals demonstrating a positive birefringence and urate crystals demonstrating a negative birefringence.

It is rare for rheumatoid arthritis to present as a large joint monoarthritis is a gentleman of this age.

Negative synovial fluid culture makes septic arthritis a less likely diagnosis.

There are five classic presentations of psoriasis (none of which fit with this scenario):

1. Symmetrical polyarthritis: 'rheumatoid pattern'
2. Asymmetric oligoarticular/pauciarticular arthritis: initial involvement of the hands and feet with dactylitis
3. Distal interphalangeal joint predominant involvement
4. Arthritis mutilans
5. Spondylitic pattern

The typical rash of psoriasis usually predates the onset of arthritis.

[Q: 3429] OnExamination 2012 - Basic Science

You are investigating the properties of a novel oral TNF-alpha antagonist in late stage clinical trials.

Which of the following would be an expected property of this agent?

- 1- Decreased endothelial reactivity
- 2- Decreased HDL cholesterol
- 3- Decreased insulin sensitivity
- 4- Decreased protein catabolism
- 5- Increased acute phase protein production

Answer & Comments

Answer: 4- Decreased protein catabolism

Chronic inflammatory disorders including those associated with elevated tumour necrosis factor (TNF) are noted to be associated with increased arteriolar stiffness and decreased endothelial reactivity.

TNF-alpha elevation is also known to be associated with increased insulin resistance and associated lipid abnormalities such as decreased high-density lipoprotein (HDL) cholesterol.

Increased acute phase protein production is a feature of chronic inflammation, as such a TNF-alpha antagonist is recognised to reduce this.

[Q: 3430] OnExamination 2012 - Basic Science

Which of the following arteries are branches of the axillary artery?

- 1- Inferior ulnar collateral artery
- 2- Internal thoracic artery
- 3- Profunda brachii artery
- 4- Subscapular artery
- 5- Superior ulnar collateral artery

Answer & Comments

Answer: 4- Subscapular artery

The internal thoracic artery arises from the subclavian artery.

The inferior and superior ulnar collateral arteries and the profunda brachii are branches of the brachial artery.

The subscapular artery arises from the axillary and is its largest branch, eventually anastomosing with the lateral thoracic and intercostal arteries.

[Q: 3431] OnExamination 2012 - Basic Science

A 24-year-old man presents with proteinuria, haematuria and sensorineural deafness.

Which of the following protein structures is likely to be abnormal?

- 1- Fibrillin
- 2- Laminin
- 3- Type 1 collagen
- 4- Type 3 collagen
- 5- Type 4 collagen

Answer & Comments

Answer: 5- Type 4 collagen

The diagnosis is Alport's syndrome, which is a disorder of type 4 collagen assembly and is inherited as an X linked disorder in 85% of cases.

Fibrillin gene abnormalities are associated with Marfan's syndrome.

Type 1 collagen disorders are associated with osteogenesis imperfecta; it is the main type of collagen in tendon and bone.

Type 3 collagen is the main component of reticular fibres.

[Q: 3432] OnExamination 2012 - Basic Science

Which of the following does N-acetylcysteine replenish?

- 1- Cystathionine
- 2- Cytochrome P450
- 3- Glucuronyl transferase
- 4- Glutathione
- 5- Sulfatase

Answer & Comments

Answer: 4- Glutathione

Acetylcysteine, the N-acetyl derivative of the naturally occurring amino acid L-cysteine, is a mucolytic agent and sulfhydryl donor acting as an antidote for paracetamol overdose.

[Q: 3433] OnExamination 2012 - Basic Science

Which of the following genetic mutations is responsible for Marfan syndrome?

- 1- Collagen
- 2- Elastin
- 3- Fibrillin
- 4- Microfilament
- 5- Microtubule

Answer & Comments

Answer: 3- Fibrillin

Marfan syndrome occurs due to a mutation in the fibrillin gene.

Most patients, who are prone to develop an aortic aneurysm as a component of Marfan syndrome, can be identified by detection of mutations in the fibrillin-1 gene.

Patients with the rarer form of Marfan syndrome, which is characterised by contractural arachnodactyly instead of loose joints, can usually be identified by detection

of a mutation in the fibrillin-2 gene that is similar in structure to the gene for fibrillin-1.

Preliminary data suggest that patients with mutations in the fibrillin-2 gene are not prone to develop aneurysms.

[Q: 3434] OnExamination 2012 - Basic Science

Suppose you are attempting to find a disease-causing gene, and you have identified a number of families in which the disease is transmitted.

If you have no knowledge of the gene product and no reasonable candidate locus, which of the following would be the first technique you would be most likely to use?

- 1- Denaturing gradient gel electrophoresis (DGGE)
- 2- DNA sequencing
- 3- Fluorescence in situ hybridisation (FISH)
- 4- Linkage analysis
- 5- Single strand conformation polymorphism (SSCP) analysis

Answer & Comments

Answer: 4- Linkage analysis

Linkage analysis is correct.

Southern blotting is a laboratory procedure in which DNA fragments that have been electrophoresed through a gel are transferred to a solid membrane such as nitrocellulose. The DNA can then be hybridised with a labelled probe and exposed to x ray film.

Somatic cell hybridisation is a physical gene-mapping technique in which somatic cells from two different species are fused and allowed to undergo cell division. Chromosomes from one species are selectively lost resulting in clones with only one or a few chromosomes from one of the species.

FISH is a molecular cytogenetic technique in which labelled probes are hybridised with chromosomes and then visualised under a fluorescence microscope.

SSCP is a technique for detecting variation in DNA sequence by running single-stranded DNA fragments through a non-denaturing gel. Fragments with differing secondary structure (conformation) caused by sequence variation will migrate at different rates.

[Q: 3435] OnExamination 2012 - Basic Science

In one gene mapping technique, denatured deoxyribonucleic acid (DNA) from metaphase chromosomes is hybridised with a radioactively labelled probe. This DNA is then exposed to film to reveal the approximate chromosomal location of the DNA in the probe.

Which technique does this best describe?

- 1- Fluorescence in situ hybridisation (FISH)
- 2- In situ hybridisation
- 3- Single strand conformation polymorphism (SSCP) analysis
- 4- Southern blotting
- 5- Somatic cell hybridisation

Answer & Comments

Answer: 2- In situ hybridisation

The technique described is 'in situ hybridisation'.

Southern blotting is a laboratory procedure in which DNA fragments that have been electrophoresed through a gel are transferred to a solid membrane, such as nitrocellulose. The DNA can then be hybridised with a labelled probe and exposed to x ray film.

Somatic cell hybridisation is a physical gene mapping technique in which somatic cells from two different species are fused and

allowed to undergo cell division. Chromosomes from one species are selectively lost, resulting in clones with only one or a few chromosomes from one of the species.

FISH is a molecular cytogenetic technique in which labelled probes are hybridised with chromosomes and then visualised under a fluorescence microscope.

SSCP is a technique for detecting variation in DNA sequence by running single-stranded DNA fragments through a non-denaturing gel. Fragments with differing secondary structure (conformation) caused by sequence variation will migrate at different rates.

[Q: 3436] OnExamination 2012 - Basic Science

A 35-year-old male is struck on the lateral aspect of his right knee by the bumper of a car travelling at low velocity.

On examination he is unable to dorsiflex the ankle, evert the foot and extend the toes. There is loss of sensation of the dorsum of the foot.

He is most likely to have damaged which structure?

- 1- Common peroneal nerve
- 2- Deep peroneal nerve
- 3- Saphenous nerve
- 4- Sural nerve
- 5- Tibial nerve

Answer & Comments

Answer: 1- Common peroneal nerve

The common peroneal nerve supplies the muscles of the peroneal and anterior compartment of the leg and sensation to the dorsum of the foot.

The deep peroneal nerve is a division of the common peroneal nerve and supplies only

the muscles of the anterior compartment of the leg.

[Q: 3437] OnExamination 2012 - Basic Science

Which of the following statements regarding the hindbrain is/are accurate?

- 1- The locus caeruleus receives fibres from the facial nerve
- 2- The medulla oblongata opens into the third ventricle
- 3- The nucleus ambiguus gives rise to the hypoglossal nerve
- 4- The pyramidal tracts decussate prior to the hindbrain
- 5- The vermis lies medial to the cerebellar hemispheres

Answer & Comments

Answer: 5- The vermis lies medial to the cerebellar hemispheres

The hindbrain comprises:

The myelencephalon (medulla oblongata and lower part of the fourth ventricle)

The metencephalon (pons, cerebellum and intermediate part of fourth ventricle) and

Isthmus rhombencephalon.

The medulla oblongata opens into the fourth ventricle.

The nucleus ambiguus gives rise to fibres of the accessory, vagus and glossopharyngeal nerves.

The locus caeruleus receives sensory fibres from the trigeminal nerve.

The three parts of the cerebellum include the vermis and the two hemispheres which are confluent. The median portion of the cerebellum is the vermis and the cerebellar hemispheres lie lateral to it.

The pyramidal tracts decussate in the inferior part of the medulla.

[Q: 3438] OnExamination 2012 - Basic Science

During a neurological examination of the upper limb you attempt to elicit the triceps reflex.

You place the patient's arm across the chest, with the elbow flexed at 90°. The triceps tendon is struck with the tendon hammer.

Which nerve (and its nerve root) are you testing?

- 1- Median nerve C6
- 2- Median nerve C7
- 3- Radial nerve C5
- 4- Radial nerve C6
- 5- Radial nerve C7

Answer & Comments

Answer: 5- Radial nerve C7

The radial nerve innervates the triceps muscle; it is primarily derived from the C7 nerve root.

The radial nerve is the motor supply to the extensor compartments of the upper limb.

The triceps muscle is the chief extensor of the forearm. Its name derives from its three heads of origin (long, lateral and medial).

It attaches into the olecranon of the ulna.

Deep tendon reflexes...

[Q: 3439] OnExamination 2012 - Basic Science

A 70-year-old woman presented with bone pains in her back, shoulders and pelvis.

Investigations reveal:

Serum corrected Calcium 2.2 mmol/L(2.2-2.6)

Serum Phosphate 0.6 mmol/L(0.8-1.4)

Serum alkaline phosphatase 160 U/L(45-105)

What further investigation would be most helpful in making the diagnosis?

- 1- DEXA bone scan.
- 2- Parathyroid hormone concentration.
- 3- Serum vitamin D concentration.
- 4- Thyroid function test.
- 5- Urine Bence Jones protein estimation

Answer & Comments

Answer: 3- Serum vitamin D concentration.

The symptoms of proximal bone pain with hypocalcaemia and low phosphate suggest a diagnosis of osteomalacia in this elderly woman. Vitamin D concentrations should therefore be measured. Serum alkaline phosphatase is typically high as it is released from bone reflecting osteoblastic activity. Serum PTH is also usually elevated and normalises gradually on response to treatment.

Hypercalcaemia would be expected in multiple myeloma, hyperparathyroidism and hyperthyroidism.

A DEXA scan would assess the bone mineral density which allows osteoporosis to be diagnosed. Due to her age, this patient may have osteoporosis, but it is unlikely to be the cause of her pain. Classically, osteoporosis in the absence of fracture, does not cause pain. Many patients with osteoporosis have concomitant disorders such as osteomalacia and osteoarthritis which cause bone pain.

[Q: 3440] OnExamination 2012 - Basic Science

Which of the following medications can cause hypomagnesaemia?

- 1- Aminophylline
- 2- Amitriptyline
- 3- Cisplatin

4- Co-trimoxazole

5- Lithium

Answer & Comments

Answer: 3- Cisplatin

Most of the body's magnesium is intracellular with only 1% being extracellular, in blood and interstitial fluid. This means that blood magnesium levels do not necessarily correspond with whole body magnesium status.

Causes of hypomagnesaemia include:

Drugs including cisplatin, diuretics, cyclosporine and cardiac glycosides

Malabsorption syndromes

Diarrhoea

Hypercalcaemia

Alcohol

Metabolic acidosis

Renal diseases - pyelonephritis, glomerulonephritis, acute tubular necrosis and interstitial nephritis.

Profound hypomagnesaemia can cause tetany, seizures and cardiac arrhythmias and needs to be treated intravenously.

Lithium can cause hypermagnesaemia.

[Q: 3441] OnExamination 2012 - Basic Science

Which of the following are antibodies to which enzymes involved in glucose metabolism may be found in primary biliary cirrhosis?

- 1- All of the following
- 2- Glucokinase (generates glucose-6-phosphate from glucose)
- 3- Lactate dehydrogenase (generates lactate from pyruvate)

- 4- Pyruvate dehydrogenase (generates acetyl-CoA from pyruvate)
- 5- Pyruvate kinase (generates pyruvate from phosphoenolpyruvate)

Answer & Comments

Answer: 4- Pyruvate dehydrogenase (generates acetyl-CoA from pyruvate)

Pyruvate dehydrogenase (PD), required for the generation of acetyl-CoA from pyruvate for entry into the tricarboxylic acid (TCA) cycle, is found in the mitochondria.

Anti-mitochondrial antibodies (AMAs) - the serological hallmark of primary biliary cirrhosis (PBC) - are often targeted against pyruvate dehydrogenase.

The other enzymes listed are involved in glycolysis, which takes place in the cytosol.

Pyruvate dehydrogenase is crucial for aerobic respiration. Inherited deficiencies / defects of PD are rare but often present with severe lactic acidosis in neonates. When this occurs, there can be no generation of acetyl-CoA for the Krebs cycle. Anaerobic glycolysis occurs, as the cell attempts to make adenosine triphosphate (ATP), but lactate is formed creating an acidosis.

In health, PD competes with pyruvate carboxylase (PC) for their common substrate, pyruvate. PD produces acetyl-CoA for the Krebs cycle, whereas PC produces oxaloacetate, a substrate for gluconeogenesis.

Acetyl-CoA regulates the balance between these two reactions (and thus the balance between anabolic and catabolic pathways) by activating PC - so that in 'energy-rich' states, where acetyl-CoA is in abundance, gluconeogenesis will be favoured.

Reference:

Ah Mew et al. MRI Features of 4 Female Patients With Pyruvate Dehydrogenase E1 alpha

Deficiency. *Pediatr Neurol* (2011) vol. 45 (1) pp. 57-9

<http://themedicalbiochemistrypage.org/tca-cycle.html> (an excellent source for biochemical pathways with diagrams).

[Q: 3442] OnExamination 2012 - Basic Science

A 43-year-old woman presents with weight gain and menstrual irregularities.

Her BMI is 29 kg/m², blood pressure is 150/90 mmHg and urinalysis shows + glucose.

Which of the following investigations should be performed initially?

- 1- 24 hour urine cortisol
- 2- Aldosterone
- 3- HbA1c
- 4- Plasma testosterone
- 5- Prolactin

Answer & Comments

Answer: 1- 24 hour urine cortisol

This history is suggestive of Cushing's syndrome: hypertension, adiposity, menstrual irregularities and impaired glucose homeostasis or diabetes. It is caused by overproduction of cortisol. Other features are recurrent infections, osteoporosis, hypokalaemia and psychiatric disturbance.

Cushing's syndrome can be challenging to diagnose as it often requires several different diagnostic tests.

The 24 hour urine free cortisol (UFC) is a good initial screening test. Borderline results can occur with stress. If the UFC is elevated, consider repeating it and consider the overnight or low-dose dexamethasone suppression tests. Investigations are then often needed to localise the cause of Cushing's syndrome.

If Cushing's syndrome is excluded, serum prolactin, testosterone and HbA1c are all

reasonable tests to do. The patient may have polycystic ovarian syndrome (PCOS) with impaired glucose tolerance or diabetes. The presence of clinical or biochemical evidence of hyperandrogenism is useful in the diagnosis of PCOS - serum testosterone would be useful here. A prolactinoma can cause menstrual disturbance but is not particularly associated with weight gain or diabetes.

The correct answer remains UFC however, as you do not want to miss Cushing's syndrome.

[Q: 3443] OnExamination 2012 - Basic Science

Which of the following statements regarding myosin is correct?

- 1- Contains an cAMP-binding sites
- 2- Forms filaments in a pentameric array with two heavy chains and three light chains
- 3- Has no function when not part of a filament
- 4- It drives smooth muscle contraction
- 5- Myosin heavy chain mutations are associated with development of familial hypertrophic cardiomyopathy

Answer & Comments

Answer: 5- Myosin heavy chain mutations are associated with development of familial hypertrophic cardiomyopathy

Myosin drives striated muscle contraction, and can be divided into two groups :

Conventional (class II myosins) which form filaments in a hexameric array of two heavy chains and two pairs of light chains.

Unconventional myosins do not form filaments and perform varied functions in a broad range of cells (for example, organelle transport, endocytosis).

Myosin contains adenosine triphosphate (ATP) and actin-binding sites.

Other myosin related genetic disorders besides the heavy chain mutations in cardiomyopathy include Carney's complex (trismus-pseudocamptodactyly), type 1b Usher syndrome and non-syndromic deafness.

[Q: 3444] OnExamination 2012 - Basic Science

A 65-year-old man with a history of myocardial infarction four years earlier was admitted with progressive shortness of breath and decreasing exercise tolerance. He has smoked 40 cigarettes per day for the last 45 years.

He takes lansoprazole, aspirin and lisinopril.

Which of the following laboratory tests would help identify the reason for his symptoms?

- 1- Brain natriuretic peptide (BNP)
- 2- Clotting screen
- 3- C reactive protein
- 4- Full blood count
- 5- Urea and electrolytes

Answer & Comments

Answer: 1- Brain natriuretic peptide (BNP)

This patient has features of heart failure which appear to be related to underlying ischaemic heart disease. The differential diagnosis is COPD, given his extensive smoking history.

Heart failure is a clinical syndrome characterised by dyspnoea, fatigue and ankle oedema. Signs which can point towards the diagnosis are pulmonary rales, pleural effusion, raised jugular venous pressure and peripheral oedema. Objective evidence is gained from echocardiogram, and raised natriuretic peptide concentration. Cardiomegaly, third heart sound and murmurs can be suggestive of cardiac failure. The European Society of Cardiology

guidelines state there must be symptoms, signs AND objective evidence before a diagnosis of heart failure can be made. It is important to always attempt to identify the underlying cause.

BNP is a biologically active peptide, which has vasodilator and natriuretic properties. It is synthesised in the cardiac ventricles and correlates with left ventricle (LV) pressure, degree of dyspnoea, and state of neurohormonal modulation. Levels increase markedly in left ventricular dysfunction, and the level correlates with symptom severity (and decrease after effective treatment). It is raised in right or left systolic or diastolic heart failure. As such, it is an important clinical marker for the diagnosis of heart failure in patients with dyspnoea that could be attributed to a number of causes. Its use as a prognostic marker, therapy guide or screening marker is under investigation. One note of caution, however, as levels can be raised in comorbid illness, age, renal failure and obesity and therefore correlation should be made with the clinical scenario.

In practice as this patient has had a previous MI, according to the current NICE guidelines he needs specialist assessment and Doppler echocardiography within 2 weeks. However, as this is not an option, BNP is the best available answer. BNP is used first line in patients who have not had a previous MI. Levels >400pg/ml warrant urgent specialist assessment and echocardiography; intermediate levels (100-400pg/ml) should be investigated within six weeks.

FBC, U&E and creatinine, CRP and clotting screen are non-specific investigations which are unlikely to directly lead to a diagnosis in this case.

[Q: 3445] OnExamination 2012 - Basic Science

Which of the following is most likely be associated with hyperkalaemia?

- 1- Bartter's syndrome
- 2- Beta adrenergic stimulation
- 3- Cushing's syndrome
- 4- Cyclosporin
- 5- Mannitol

Answer & Comments

Answer: 4- Cyclosporin

Common causes of hyperkalaemia include:

Impaired renal excretion: renal failure, hyporeninaemic hypoaldosteronism (type IV renal tubular acidosis), Addison's, C-21 hydroxylase deficiency.

Cellular changes: acidosis, rhabdomyolysis, tumour lysis, malignant hyperthermia, burns.

Drugs: potassium retaining diuretics, angiotensin-converting enzyme (ACE) inhibitors, non-steroidal anti-inflammatory drugs (NSAIDs), cyclosporin, succinyl choline, β -blockers.

[Q: 3446] OnExamination 2012 - Basic Science

Which of the following statements is true concerning gamma glutamyl transferase (GGT)?

- 1- Increased GGT is found in fatty liver
- 2- Isolated elevation of gamma GT in a patient with prostatic carcinoma Indicates the presence of hepatic metastases.
- 3- It is a better indicator of infectious hepatitis than of cholestasis
- 4- It is only present in the liver
- 5- Serum activity is typically elevated in pregnancy

Answer & Comments

Answer: 1- Increased GGT is found in fatty liver

GGT is found in muscle, prostate as well as liver.

Increased levels of GGT are found in cholestatic liver disease and in hepatocellular disease when there is an element of cholestasis.

Levels are increased with chronic intake of excess alcohol and with certain drugs (especially phenytoin), as a result of enzyme induction. Pancreatitis and prostatitis may also be associated with increased levels.

Levels may be normal early in the course of acute hepatocellular damage, for example, acute viral hepatitis, paracetamol hepatotoxicity.

Elevations in pregnancy would suggest liver disease.

[Q: 3447] OnExamination 2012 - Basic Science

A 46-year-old man was seen for an insurance medical examination.

He was entirely asymptomatic, but his serum urate concentration was noted to be 0.5 mmol/L (0.23 - 0.46).

What is the most appropriate management for this patient?

- 1- Allopurinol
- 2- Colchicine
- 3- Ibuprofen
- 4- Lifestyle intervention
- 5- Sulphinpyrazone

Answer & Comments

Answer: 4- Lifestyle intervention

Uric acid is the major product produced from the catabolism of purines, adenosine monophosphate (AMP) and guanosine monophosphate (GMP) from nucleic acids.

GMP and AMP are catabolised by a series of enzymes which remove a single phosphate group and the ribose sugar, eventually forming xanthine. Xanthine is then converted to uric acid by the enzyme xanthine oxidase. Uric acid can then be excreted by the kidneys.

When uric acid levels are high, there is a risk of developing gout, which causes monoarticular inflammation, gouty arthropathy and tophaceous deformity. Xanthine oxidase inhibitors are used in the treatment of gout, to reduce the amount of uric acid formed.

The patient above requires lifestyle advice about reducing intake of substances containing high purines (including some alcohol and red meat). Should he become symptomatic, treatment would be advisable. In acute gout, treatment is with NSAIDs or other anti-inflammatories such as colchicine.

A xanthine oxidase inhibitor such as allopurinol should be started after the acute attack to reduce the risk of recurrence.

Causes of hyperuricaemia include:

Increased formation of uric acid:

Primary:

Idiopathic and inherited metabolic disease

Secondary:

Alcohol

Psoriasis

Increased nucleic acid turnover: leukaemia and myeloma

Tissue hypoxia

Excess dietary purine intake.

Decreased excretion of uric acid:

Primary:

Idiopathic

Secondary:

Acute or chronic renal disease
Organic acidosis: lactate, ketones
Lead poisoning
Drugs: aspirin and thiazides
Down's syndrome.

[Q: 3448] OnExamination 2012 - Basic Science

Metabolic alkalosis is characteristically found in which of the following?

- 1- An infusion of sodium chloride
- 2- Ileostomy
- 3- Mineralocorticoid deficiency
- 4- Pyloric stenosis
- 5- Salicylate poisoning

Answer & Comments

Answer: 4- Pyloric stenosis

Pyloric stenosis is associated with vomiting and the loss of stomach content - hence a metabolic alkalosis.

Normal saline has a pH of 5 and may produce a mild metabolic acidosis with significant infusions.

Ileostomy may be associated with a loss of bicarbonate ions and hence acidosis.

Mineralocorticoid excess (Conn's syndrome) is also associated with a metabolic alkalosis.

Salicylates are themselves acidic and produce a metabolic acidosis.

[Q: 3449] OnExamination 2012 - Basic Science

A 75-year-old man presents with a long history of shortness of breath and ankle oedema.

His serum biochemistry shows sodium 122 mmol/L (137-144) and potassium of 2.9

mmol/L (3.5-4.9). He now complains of weakness.

Which of the following is likely to explain the above biochemical picture?

- 1- Addison's disease
- 2- Diuretic therapy
- 3- Nephrotic syndrome
- 4- Primary hyperaldosteronism
- 5- SIADH

Answer & Comments

Answer: 2- Diuretic therapy

The long history of his symptoms and serum biochemistry suggests that his condition is due to treatment with furosemide for congestive cardiac failure (CCF).

Primary hyperaldosteronism is associated with high aldosterone, suppressed renin, low potassium and normal/high sodium. Clinically it causes hypertension and is often asymptomatic.

Addison's disease - glucocorticoid and mineralocorticoid deficiency - is classically associated with low sodium and high potassium.

Nephrotic syndrome is not associated with hyponatraemia and hypokalaemia in early stages although if there is reduced glomerular filtration rate (GFR) hyperkalaemia can result. Glomerular disease allows the release of proteins into the urine but electrolytes are reabsorbed.

SIADH would not explain the hypokalaemia.

[Q: 3450] OnExamination 2012 - Basic Science

A 72-year-old man is found to have the following biochemistry:

Calcium 1.98 mmol/L (2.2-2.6)

Phosphate 0.55 mmol/L (0.8-1.4)

Alkaline phosphatase 450 U/L (60-110)

Which of the following is the most likely explanation for his biochemistry?

- 1- Osteomalacia
- 2- Osteoporosis
- 3- Paget's disease
- 4- Renal failure
- 5- Tertiary hyperparathyroidism

Answer & Comments

Answer: 1- Osteomalacia

Osteomalacia is associated with low calcium and phosphate with raised alkaline phosphatase. Parathyroid hormone (PTH) would be high.

Serum biochemistry is normal in osteoporosis, although alkaline phosphatase can be elevated following a fracture.

Paget's disease is associated with normal calcium and phosphate with raised alkaline phosphatase.

In chronic renal failure there is inadequate 1-alpha hydroxylation of vitamin D, preventing the formation of active 1,25 dihydroxy vitamin D. This results in a low serum calcium and a compensatory high PTH (secondary and tertiary hyperparathyroidism). Phosphate is elevated due to altered excretion.

[Q: 3451] OnExamination 2012 - Basic Science

An Afro-Caribbean male aged 48 years presents with gradual onset of exertional dyspnoea, non-productive cough, malaise, weight loss and polyarthralgia.

Schirmer's test indicates a dry eye. x Ray of the hand shows punched out osteopenic lesions.

Which of the following investigations is unlikely to be helpful in establishing the diagnosis of this condition?

- 1- Quantitative immunoglobulins.
- 2- Serum calcium
- 3- Serum phosphorus
- 4- Thallium scan
- 5- Urea and electrolytes

Answer & Comments

Answer: 4- Thallium scan

This condition is sarcoidosis.

Serum calcium, serum phosphorus, chem7 and chem 20 and quantitative immunoglobulins are all used in establishing the diagnosis. Gallium scan is helpful in sarcoidosis. (Radiology of extrathoracic sarcoid ...)

Gallium scan vs. Thallium scan.

Gallium scan (radioactive ⁶⁷Ga) is used to detect inflammation - such as in inflammatory disorders or malignancy.

Thallium (radioactive ²⁰¹Tl) is a potassium analogue and is used to demonstrate areas of poor perfusion. It is particularly used in cardiology to detect areas of ischaemia.

[Q: 3452] OnExamination 2012 - Basic Science

With which of the following is lipoprotein lipase deficiency associated?

- 1- Abetalipoproteinaemia
- 2- Combined hyperlipidaemia
- 3- Familial combined hyperlipidaemia
- 4- Familial hypercholesterolaemia
- 5- Marked hypertriglyceridaemia

Answer & Comments

Answer: 5- Marked hypertriglyceridaemia

Lipoprotein lipase deficiency is autosomal recessive and associated with increased

chylomicrons and marked hypertriglyceridaemia.

[Q: 3453] OnExamination 2012 - Basic Science

A 37-year-old man presents with an anterior myocardial infarction.

He admits to smoking 20 cigarettes per day. His lipid screening on admission reveals total cholesterol of 9.5 mmol/l, triglycerides are at the upper end of the normal range.

Which of the following is the most likely abnormality?

- 1- Apolipoprotein A mutation
- 2- Apolipoprotein B mutation
- 3- HDL receptor mutation
- 4- LDL receptor mutation
- 5- Triglyceride receptor mutation

Answer & Comments

Answer: 4- LDL receptor mutation

Abetalipoproteinaemia leads to the absence of low-density lipoprotein (LDL).

Apolipoprotein A mutations result in defective high-density lipoprotein (HDL).

HDL receptor mutations result in increased levels of HDL, triglyceride receptor mutations in increased levels of triglycerides.

[Q: 3454] OnExamination 2012 - Basic Science

You are doing a stint in chemical pathology and are asked to review the evening's significantly abnormal results.

One set from a 72-year-old man particularly concerns the laboratory staff:

Investigations show:

Haemoglobin 12.9 g/dl (13.5-17.7)

White cell count $8.0 \times 10^9/L$ (4-11)

Platelets $158 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 2.5 mmol/l (3.5-5)

Bicarbonate 14 mmol/l (22-30)

Creatinine 133 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely diagnosis?

- 1- Addison's disease
- 2- Bartter's syndrome
- 3- Conn's syndrome
- 4- Gitelman's syndrome
- 5- Ureteric diversion

Answer & Comments

Answer: 5- Ureteric diversion

Ureteric diversion results in metabolic acidosis because implantation of the ureters into the sigmoid colon or a vesicocolic leads to absorption of Cl^- in exchange for HCO_3^- across the bowel mucosa. Absorption of urinary NH_4^+ in the sigmoid colon may also contribute to the development of acidosis as metabolism of the ammonium in the liver results in production of H^+ .

Addison's can result in hyperkalaemia, hyponatraemia and metabolic acidosis.

Conn's leads to hypokalaemic metabolic alkalosis.

Bartter's and Gitelman's also lead to hypokalaemic metabolic alkalosis in the absence of hypertension in contrast to Conn's.

[Q: 3455] OnExamination 2012 - Basic Science

A pregnant woman is referred with an elevated alkaline phosphatase (ALP) level. Her other liver function tests are normal. She is otherwise well.

What is the most likely cause?

- 1- Autoimmune hepatitis
- 2- Bone metastases
- 3- Paget's disease
- 4- Placental production of ALP
- 5- Transient hyperphosphatasia of infancy

Answer & Comments

Answer: 4- Placental production of ALP

Alkaline phosphatase is a common part of the liver function tests and is an enzyme occurring in many different tissues throughout the body. The causes of an elevated ALP are therefore quite diverse.

In practice, most abnormalities of ALP concentration relate to isoenzymes from the liver or bone but the placenta also can make ALP. Thus in pregnant women ALP levels are usually two to three times higher than non-pregnant values: this is quite normal.

In childhood elevated ALP levels signify bone growth and are usually physiological, not pathological. Transient hyperphosphatasia of infancy involves more dramatic elevations of ALP (up to ten times normal) which is thought to be benign in nature and resolves after three to four months. It affects children aged around 2-4-years-old.

Liver disease: ALP is closely associated with the biliary canaliculi in the liver and will rise with any form of hepatobiliary obstruction, particularly with extrahepatic causes such as pancreatic carcinoma or a gallstone in the common bile duct.

When drainage of bile is obstructed ALP synthesis increases dramatically. Liver diseases which predominantly cause hepatocellular damage (such as viral or autoimmune hepatitis) rather than biliary obstruction will cause a lesser degree of ALP elevation.

Bone disease: ALP aids in the calcification process in bone and is found in osteoblasts.

ALP can therefore be abnormal in any disease affecting bone turnover and calcification, including Paget's disease, vitamin D deficiency, primary and secondary hyperparathyroidism, bone malignancies and fracture healing.

Paget's disease involves increased bone turnover and is a relatively common finding in older patients (more than 50-years-old). It can be asymptomatic or can be associated with tender bone/skull over-growth, sensorineural deafness, pathological fractures and rarely, high output cardiac failure.

[Q: 3456] OnExamination 2012 - Basic Science

The enterohepatic circulation primarily involves which part of the gastrointestinal tract?

- 1- Anus
- 2- Jejunum
- 3- Pancreas
- 4- Rectosigmoid junction
- 5- Terminal ileum

Answer & Comments

Answer: 5- Terminal ileum

The enterohepatic circulation is a means of recycling some of the waste materials excreted in the bile.

At the level of the terminal ileum, bile salts and some of the bilirubin derivatives are reabsorbed and return to the liver in the portal circulation. This process is regulated by a number of transporter proteins both in the liver canaliculi and in the ileum.

Bacterial flora in the colon also facilitate the enterohepatic circulation of bilirubin derivatives. Some bacteria contain the enzyme beta-glucuronidase which converts conjugated bilirubin to unconjugated

bilirubin, which is more lipid-soluble and more easily reabsorbed.

[Q: 3457] OnExamination 2012 - Basic Science

Oxygen-requiring metabolic reactions occur predominantly in which type of liver cells?

- 1- Ito (stellate) cells
- 2- Zone 1 hepatocytes
- 3- Kupffer cells
- 4- Zone 2 hepatocytes
- 5- Zone 3 hepatocytes

Answer & Comments

Answer: 2- Zone 1 hepatocytes

The liver is made up of many small subunits called acini. Each acinus has a dual blood supply from firstly, a branch of the hepatic artery (oxygen rich) and secondly, a branch of the portal vein (solute rich). The blood from these flows through the hepatic sinusoids which allow quite free movement of solutes and oxygen from the blood cells into the hepatocytes. Eventually the blood joins a venule and drains into the hepatic vein and back to the systemic circulation.

Hepatocytes near the hepatic arterial supply and portal vein supply (periportal region) are called zone 1 hepatocytes. Zone 3 hepatocytes are furthest from the arterial supply and closest to the branch of the hepatic vein (perivenular region). Zone 2 hepatocytes are in the middle.

Zone 1 hepatocytes receive an oxygen-rich, solute-rich supply which makes them highly metabolically active, but more at risk of damage through the effects of toxins coming from the gut. Most of the highly-oxygen-requiring reactions occur here, including the electron transport chains, Krebs' cycle, fatty acid oxidation and urea synthesis.

Zones 2 and 3 receive less oxygen and tend to be involved in reactions requiring little or no oxygen, such as glycolysis.

Ito cells store fats and vitamin A and are involved in production of connective tissue. In liver disease, they are thought to be fundamental in the development of fibrosis and cirrhosis.

Kupffer cells are part of the reticuloendothelial system and are specialised macrophages. They are involved in the breakdown of haemoglobin and the removal of haem for further metabolism in the hepatocytes. Kupffer cells also have a role in immunity.

[Q: 3458] OnExamination 2012 - Basic Science

Which of the following statements regarding glucagon-like peptide 1 (GLP-1) effects in humans is correct?

- 1- GLP-1 increases the rate of gastric emptying
- 2- GLP-1 inhibits glucose-induced insulin secretion
- 3- GLP-1 is secreted predominantly by pancreatic islet cells
- 4- GLP-1 reduces satiety in the brain
- 5- GLP-1 suppresses postprandial glucose secretion

Answer & Comments

Answer: 5- GLP-1 suppresses postprandial glucose secretion

GLP-1 is an incretin hormone which promotes glucose induced insulin release from the pancreatic beta cell.

GLP-1 delays the rate of gastric emptying, and promotes satiety and reduces the appetite in the brain.

GLP-1 enhances glucose dependent beta cell secretion of insulin and is predominantly secreted by the L cells of ileum and colon.

GLP-1 suppresses glucagon secretion from pancreatic a-cells in a glucose-dependent manner, suppressing hepatic glucose output, thus lowering plasma glucose levels.

Currently the synthetic GLP-1 analogue, exenatide is licensed for combination therapy in the management of type 2 diabetes.

[Q: 3459] OnExamination 2012 - Basic Science

Apoptosis is induced by which of the following?

- 1- Activation of caspases
- 2- Antibodies
- 3- DNA synthesis
- 4- Necrosis
- 5- The MAP kinase pathway

Answer & Comments

Answer: 1- Activation of caspases

A key event in the initiation of apoptosis is the activation of a cascade of cysteine-aspartate specific proteases known as caspases.

[Q: 3460] OnExamination 2012 - Basic Science

A 17-year-old female is affected by an inherited disorder. She has two brothers who are unaffected. She has two sisters both are affected. Her father is affected but not her mother.

Which of the following modes of inheritance is the best explanation?

- 1- Autosomal dominant
- 2- Autosomal recessive
- 3- Mitochondrial

4- X linked dominant

5- X linked recessive

Answer & Comments

Answer: 4- X linked dominant

This is a tricky question and the crucial part is recognising that X linked dominant conditions are transmitted by a father to all his daughters and that, on balance, this is a better explanation of the genetics than the tenuous assertion that an autosomal dominant condition has by chance affected three daughters but neither of two sons.

X linked dominant disorders are rare (for example, vitamin D-resistant rickets). They affect both sexes but females more than males.

All children of a homozygous mother are affected.

Half the sons and half the daughters inherit the disorder from an affected mother with the trait.

An affected father passes the disease to all his daughters but none of his sons - as in this example.

[Q: 3461] OnExamination 2012 - Basic Science

Which of the following disorders is characterised by an autosomal recessive mode of inheritance?

- 1- Achondroplasia
- 2- Congenital adrenal hyperplasia
- 3- Familial hypercholesterolaemia
- 4- Hereditary haemorrhagic telangiectasia
- 5- Huntington's disease

Answer & Comments

Answer: 2- Congenital adrenal hyperplasia

All the others are autosomal dominant.

[Q: 3462] OnExamination 2012 - Basic Science

A 34-year-old man with polycystic kidney disease attends the transplant clinic with his 19-year-old brother.

His most recent creatinine has been measured at 342 $\mu\text{mol/l}$, and he is on several anti-hypertensive drugs and erythropoietin injections to maintain his haemoglobin, which was recently measured as 10.4 g/l.

On examination his BP is 149/87 mmHg. Other findings are consistent with chronic renal failure. His father had end stage renal failure for some years before his death.

Which of the following most accurately reflects the chances of his brother being able to donate a kidney to him?

- 1- 0%
- 2- 25%
- 3- 33%
- 4- 50%
- 5- 100%

Answer & Comments

Answer: 4- 50%

Polycystic kidney disease (PCKD) carries an autosomal dominant inheritance pattern. As such, with one affected parent, each child has a 50% chance of inheriting the PCKD gene.

Whilst ultrasound is very sensitive in detection of PCKD in patients over 20, in those under 20 it is not 100% accurate.

It may not seem immediately obvious to consider a family member as a potential donor, but they may be a valuable source for a kidney in this situation.

[Q: 3463] OnExamination 2012 - Basic Science

A 25-year-old male presents with symptoms of gait ataxia and pes cavus. His father

developed similar symptoms at the age of 36.

Which of the following genetic phenomena explains the age of his presentation?

- 1- Anticipation
- 2- Complex traits
- 3- Epistasis
- 4- Expansion
- 5- Microdeletion

Answer & Comments

Answer: 1- Anticipation

A phenomenon whereby the symptoms of a condition appear at an earlier age when inherited in the next generation is termed anticipation.

These conditions are almost exclusively associated with trinucleotide repeat sequences and examples are Huntington's disease, myotonic dystrophy, and Friedreich's ataxia, as is probably the case in this patient.

[Q: 3464] OnExamination 2012 - Basic Science

Which of the following is a polygenic disorder?

- 1- Ankylosing spondylitis
- 2- Erythropoietic porphyria
- 3- Fragile X syndrome
- 4- Huntington's disease
- 5- Pendred's syndrome

Answer & Comments

Answer: 1- Ankylosing spondylitis

Unlike the other conditions, no one specific genetic defect has been identified to account for ankylosing spondylitis.

Huntington's chorea is an autosomal dominant condition.

Fragile X syndrome is due to a trinucleotide repeat at the FMR 1 gene on the X chromosome.

Erythropoietic porphyria is an autosomal recessive condition, as is Pendred's syndrome.

[Q: 3465] OnExamination 2012 - Basic Science

Which one of the following conditions is a polygenic disorder?

- 1- Amyotrophic lateral sclerosis (ALS)
- 2- Congenital adrenal hyperplasia (CAH)
- 3- Friedreich's ataxia
- 4- Huntington's disease
- 5- Klinefelter's syndrome

Answer & Comments

Answer: 1- Amyotrophic lateral sclerosis (ALS)

All the other conditions are associated with a specific gene defect - CAH and Friedreich's being autosomal recessive with Huntington's being dominant.

Klinefelter's is due to a chromosomal abnormality, XXY.

No specific defect has been detected thus far with ALS.

[Q: 3466] OnExamination 2012 - Basic Science

With respect to lipoprotein transport and metabolism in the body, the following statements are correct, except which?

- 1- Arterial walls contain cells with LDL receptors
- 2- Cholesterol is required for the formation of red blood cell membranes
- 3- Chylomicrons are synthesised in the liver
- 4- HDL is assembled in the extracellular space

- 5- VLDL transformation to LDL occurs in the liver

Answer & Comments

Answer: 3- Chylomicrons are synthesised in the liver

Chylomicrons are formed in the gut from exogenous triacylglycerols and cholesterol.

They are released into the lymph and thereby enter the blood.

They are not formed in the liver.

[Q: 3467] OnExamination 2012 - Basic Science

A 59-year-old woman has had insulin dependent diabetes mellitus for over two decades. The degree of control of her disease is characterised by the laboratory finding of a HbA1c of 10.1%.

She complains of repeated episodes of abdominal pain following meals. These episodes have become more frequent and last for longer periods over the last couple of months.

On physical examination, there are no abdominal masses and she has no enlarged liver, spleen or kidneys and no tenderness to palpation.

Which of the following findings is most likely to be present?

- 1- Acute pancreatitis
- 2- Chronic renal failure
- 3- Hepatic infarction
- 4- Mesenteric artery occlusion
- 5- Ruptured aortic aneurysm

Answer & Comments

Answer: 4- Mesenteric artery occlusion

Diabetes - especially type 2 diabetes - is associated with macrovascular disease.

Smoking is a further risk factor for macrovascular atherosclerosis.

After a meal splanchnic blood flow is increased. If the mesenteric artery is occluded the lack of blood flow to the bowel will produce ischaemic type pain.

Chronic renal failure may be present but would not cause post prandial pain.

Ruptured aortic aneurysm would normally present acutely with hypotension, cold lower limbs with reduced pulses and a pulsatile, tender abdominal mass.

Pancreatitis is unlikely given the history and the lack of epigastric tenderness.

Hepatic infarction should lead to right upper quadrant pain.

[Q: 3468] OnExamination 2012 - Basic Science

In meiosis which of the following is true?

- 1- Anaphase lag results in one of the two daughter cells receiving an extra part of one chromosome.
- 2- At the beginning of meiosis 2, each cell contains 23 single chromosomes.
- 3- DNA replication occurs during meiosis 1.
- 4- Non-disjunction at mitosis (meiosis 2) results in mosaicism.
- 5- The incidence of Down's syndrome due to translocation increases with increasing maternal age.

Answer & Comments

Answer: 4- Non-disjunction at mitosis (meiosis 2) results in mosaicism.

Meiosis is the form of cell division that produces gametes. It is divided into two parts, meiosis 1 and meiosis 2.

Deoxyribonucleic acid (DNA) replication occurs before meiosis 1, and the cell begins

division with twice the normal cellular amount of DNA.

In meiosis 1, each daughter cell gets one of the duplicated chromosomes of each pair. At the beginning of meiosis 2, each cell contains 23 chromosomes each with a duplicated pair of chromatids.

In meiosis 2, the duplicated pair separate and each daughter cell ends up with one of each of the 23 chromosomes (4 haploid daughter cells).

Two common errors of cell division occurring during meiosis are non-disjunction (2 chromosomes fail to separate, so both copies of the chromosome go to one of the daughter cells); and anaphase lag in which a chromatid is lost because it fails to move quickly enough during anaphase to become incorporated into one of the new daughter cells.

In Down's syndrome, non-disjunction accounts for 94% of cases. The incidence of this increases with increasing maternal age. Five per cent of cases are due to translocation, and 1% to mosaicism.

[Q: 3469] OnExamination 2012 - Basic Science

Regarding benign essential tremor which of the following is true?

- 1- Alcohol improves the tremor
- 2- Is autosomal recessive in inheritance
- 3- Is present characteristically at rest
- 4- Occurs in liver disease
- 5- Occurs with lesion in sub thalamus

Answer & Comments

Answer: 1- Alcohol improves the tremor

There is no tremor at rest, but a rhythmic oscillation develops when the patient holds the arms outstretched.

A positive family history is obtained in over half of such patients and the pattern of inheritance in such families indicates an autosomal dominant trait.

Alcohol suppresses essential tremor, but the mechanism responsible is unknown.

[Q: 3470] OnExamination 2012 - Basic Science

A 15-year-old boy comes to the dermatology clinic as his parents are concerned about some changes they have noticed in his skin. He is from a travelling community, and as such his parents have previously shunned medical services.

On examination you notice that he has a number of facial and periungual fibromata. He also has a number of hypomelanotic areas (at least four) on examination of his skin. You also notice gingival fibromata and pitting of his tooth enamel on examination of his mouth.

On which chromosome is the abnormality associated with this disease likely to be found?

- 1- Chromosome 2
- 2- Chromosome 6
- 3- Chromosome 9
- 4- Chromosome 11
- 5- Chromosome 12

Answer & Comments

Answer: 3- Chromosome 9

This boy has tuberous sclerosis, which is inherited in autosomal dominant fashion, with responsible defects having been identified on both chromosome 9 and chromosome 16. These chromosomes carry codes for hamartin and tuberin, protein gene products which are responsible for regulation of cell growth.

Most of the tumours which are produced in tuberous sclerosis are hamartomas, and various phenotypes of the disease occur, with some parents of patients having much more subtle features than those seen in their children.

[Q: 3471] OnExamination 2012 - Basic Science

Autosomal recessive conditions include which of the following?

- 1- Huntington's chorea
- 2- Manic depression
- 3- Turner's syndrome
- 4- Vitamin D resistant rickets
- 5- Wilson's disease

Answer & Comments

Answer: 5- Wilson's disease

Vitamin D resistant rickets are X linked dominant.

No linkage has been established for a particular gene in manic depressive disorder.

[Q: 3472] OnExamination 2012 - Basic Science

Which of the following is not true regarding the polymerase chain reaction?

- 1- It can be used to detect the presence of viral DNA in human disease
- 2- It is used to amplify DNA but not RNA
- 3- It utilises the thermostable properties of Taq DNA polymerase
- 4- Synthetic short DNA primers which flank the sequence of interest are required to initiate the amplification
- 5- The amount of DNA required makes it unsuitable for early prenatal diagnosis

Answer & Comments

Answer: 5- The amount of DNA required makes it unsuitable for early prenatal diagnosis

Reverse transcription polymerase chain reaction (rt-PCR) is used to amplify RNA rather than PCR specifically.

Preimplantation diagnosis uses IVF and genetic analysis of 3-day-old embryos before selective transfer of unaffected embryos to uterus.

[Q: 3473] OnExamination 2012 - Basic Science

Mutation in which of the following is associated with Alport syndrome?

- 1- Collagen type I gene
- 2- Collagen, type IV, alpha 5 gene
- 3- Fibrillin- gene
- 4- FMR-1 gene
- 5- Type II procollagen gene

Answer & Comments

Answer: 2- Collagen, type IV, alpha 5 gene

Mutations in the COL4A5 gene cause approximately 80% of Alport syndrome cases.

Several hundred different mutations have been identified, the majority of which cause a change in the sequence of amino acids (the building blocks of proteins) in a region of the alpha5(IV) collagen chain that is critical for combining with other type IV collagen chains.

Other mutations severely decrease or prevent the production of the alpha5(IV) chains.

As a result, there is a serious deficiency of the type IV collagen network in the basement membranes of the kidney, inner ear, and eye.

[Q: 3474] OnExamination 2012 - Basic Science

A 29-year-old male presents to you seeking advice regarding starting a family.

He has common variable immunodeficiency and wants to know what is the risk of passing this on to his children?

- 1- Less than 5%
- 2- 25%
- 3- 33%
- 4- 50%
- 5- Over 70%

Answer & Comments

Answer: 1- Less than 5%

Common variable immunodeficiency involves low levels of most or all of the immunoglobulin classes, a lack of B lymphocytes or plasma cells that are capable of producing antibodies, and is associated with frequent bacterial infections.

The cause of CVID is unknown - a family member may be affected in approximately 20% but there is no clear pattern of inheritance.

[Q: 3475] OnExamination 2012 - Basic Science

Which of the following abnormalities is associated with short stature?

- 1- 45, XO karyotype
- 2- 47, XXY karyotype
- 3- 47 XYY karyotype
- 4- Fragile X syndrome
- 5- Homocystinuria

Answer & Comments

Answer: 1- 45, XO karyotype

Turner's syndrome, 45 XO, is characteristically associated with short stature.

Klinefelter's is associated with tall stature.

In Fragile X, height is usually unaffected and homocystinuria may have a Marfan's habitus.

[Q: 3476] OnExamination 2012 - Basic Science

Which of the following is characteristically inherited in an autosomal recessive manner?

- 1- Achondroplasia
- 2- Adult polycystic kidney disease (APKD)
- 3- C1 esterase deficiency
- 4- Familial hypercholesterolaemia
- 5- Friedreich's ataxia

Answer & Comments

Answer: 5- Friedreich's ataxia

Achondroplasia, APKD, C1 esterase deficiency (hereditary angio-oedema) and familial hypercholesterolaemia are usually inherited as autosomal dominant traits.

Friedreich's ataxia is characteristically an autosomal recessive inheritance.

[Q: 3477] OnExamination 2012 - Basic Science

In X linked recessive inheritance, which of the following is true?

- 1- Daughters of affected males will all be carriers
- 2- Each daughter of a female carrier has a 1:4 risk of being a carrier
- 3- Each son of a female carrier has a 1:4 risk of being affected
- 4- The family history is often positive since new mutations are rare
- 5- The male to female ratio is 2:1

Answer & Comments

Answer: 1- Daughters of affected males will all be carriers

Over 250 X linked recessive disorders have been described.

The commonest include:

Red/green colour blindness

Duchenne and Becker muscular dystrophies

Fragile X syndrome

G6PD deficiency

Haemophilias A and B

Hunter's syndrome.

The abnormal gene is carried on the X chromosome, and in the carrier female, the normal allele on her other X chromosome protects her from the disease. Since the male does not have this protection, he manifests the disease.

In X linked inheritance therefore:

Males are all affected

Females only occasionally show mild sign of disease

Each son of a female carrier has a 1:2 chance of being affected

Each daughter of a female carrier has a 1:2 risk of being a carrier

Daughters of affected males will all be carriers, but sons of affected males will not be affected since the Y chromosome is derived from father.

The family history may be negative, however, since new mutations are fairly common.

Carrier females can be identified from time to time from mild clinical manifestations and from specific tests such as biochemical markers, for example, creatine kinase in Duchenne muscular dystrophy.

[Q: 3478] OnExamination 2012 - Basic Science

Which of the following disorders is characterised by an autosomal dominant mode of inheritance?

- 1- Beta-thalassaemia
- 2- Cystic fibrosis
- 3- Marfan syndrome
- 4- Wilson's disease
- 5- Xeroderma pigmentosa

Answer & Comments

Answer: 3- Marfan syndrome

Apart from Marfan syndrome, all the other listed options are autosomal recessive.

[Q: 3479] OnExamination 2012 - Basic Science

You are reviewing the results of a clinical trial of a new agent for treating type 2 diabetes mellitus. There are a number of analyses presented as part of the study.

Which of the following would be considered the most robust?

- 1- All patients who took one dose of medication
- 2- Intention to treat
- 3- One month completer
- 4- Per protocol
- 5- Trial completer

Answer & Comments

Answer: 2- Intention to treat

The intention to treat (ITT) analysis contains all the patients randomised to a particular therapy regardless of whether they received it or not. ITT is considered to be the analysis which is least subject to bias.

Completer analyses, whether they took one dose of medication, one month of medication or completed the study, are subject to degrees of bias.

A per protocol analysis may exclude patients who suffered an event but then did not follow the protocol accurately, for example, a patient treated with the diabetes agent who was admitted to hospital, but missed one to two doses of medication.

[Q: 3480] OnExamination 2012 - Basic Science

One of the scientists at your university claims to have discovered a new mutation screen which is useful for the diagnosis of a particular subtype of chronic myeloid leukaemia (CML).

The prevalence of this subtype is 10% of all cases of CML, and the test has a sensitivity of 100% with a specificity of 97%.

Which of the following approximates most closely to the positive predictive value?

- 1- 100%
- 2- 97%
- 3- 77%
- 4- 27%
- 5- 10%

Answer & Comments

Answer: 3- 77%

Out of every 100 patients screened with CML, you would expect 10 of them to have the particular subtype (true positives). False positives will be 3/100.

The positive predictive value is the percentage of true positives out of total positives, which is

$$10 / 13 = 77\%.$$

The negative predictive value is the percentage of true negatives out of total negatives.

[Q: 3481] OnExamination 2012 - Basic Science

A 23-year-old male is diagnosed with diabetes. He has frontal balding, and tells you that he has previously been diagnosed with a cardiomyopathy.

Which of the following genetic phenomena is associated with this genetic condition?

- 1- Chromosome instability
- 2- Deletion
- 3- Epistasis
- 4- Microdeletion
- 5- Trinucleotide repeats

Answer & Comments

Answer: 5- Trinucleotide repeats

The suggestion here is that the patient has myotonic dystrophy.

Myotonic dystrophy is autosomal dominant and exhibits anticipation as the number of trinucleotide repeats undergo triplet expansion, resulting in the disease presenting at a younger age, or with greater disease severity along the generations.

Examples of chromosome instability syndromes are:

Fanconi anaemia

Ataxia telangiectasia

Bloom syndrome.

[Q: 3482] OnExamination 2012 - Basic Science

Mutation in which of the following is associated with Ehlers-Danlos syndrome?

- 1- Collagen type 1 gene

- 2- FGFR3 gene
- 3- Fibrillin- gene
- 4- FMR-1 gene
- 5- Type II procollagen gene

Answer & Comments

Answer: 1- Collagen type 1 gene

Mutations in the following genes cause Ehlers-Danlos syndrome:

ADAMTS2

COL1A1

COL1A2

COL3A1

COL5A1

COL5A2

PLOD1

TNXB.

Ehlers-Danlos occurs in 1:5000 people worldwide.

In view of the wide number of mutations that can cause Ehlers-Danlos syndrome, this is a very heterogeneous condition.

FGFR3 is implicated in achondroplasia

Fibrillin gene in Marfan's syndrome and

FMR-1 gene fragile X mental retardation 1.

[Q: 3483] OnExamination 2012 - Basic Science

Mutation in which of the following is associated with Marfan's syndrome?

- 1- Collagen type 1 gene
- 2- Collagen type 5 gene
- 3- Fibrillin-1 gene
- 4- FMR-1 gene
- 5- Type II procollagen gene

Answer & Comments

Answer: 3- Fibrillin-1 gene

Mutation in the fibrillin-1 gene is thought to be responsible for Marfan's syndrome.

In Marfan's syndrome the lack of normal fibrillin-1 leads to overactivity of transforming growth factor type beta

(TGF- β) in the wall of the aorta and the heart valves, leading to damage and destruction to the connective tissue which weakens that aortic wall and heart valves causing them to stretch.

Type 1 collagen gene defects are found in osteogenesis imperfecta and type 3 in Ehlers-Danlos syndrome.

Type II procollagen defect is found in hereditary spodyloarthropathy.

[Q: 3484] OnExamination 2012 - Basic Science

A 22-year-old female is diagnosed with cystinuria following recurrent episodes of renal colic.

Which of the following is characteristic of cystinuria?

- 1- Autosomal dominant inheritance
- 2- Cataracts
- 3- Cystine deposition within the liver
- 4- Premature coronary artery disease
- 5- Radio-opaque renal calculi

Answer & Comments

Answer: 5- Radio-opaque renal calculi

Cystinuria is an autosomal recessive condition associated with the inadequate reabsorption of cystine (as well as ornithine, arginine, and lysine; useful mnemonic COAL) in the nephron causing nephrolithiasis. The stones are at least partially radio-opaque.

It accounts for less than 3% of renal calculi and has an incidence of 1 in 2,500.

The foundation of cystine stone prevention is adequate hydration and urinary alkalinisation.

[Q: 3485] OnExamination 2012 - Basic Science

A 28-year-old lady presents with multiple cafe au lait spots.

A diagnosis of neurofibromatosis (NF) type 1 is made.

Which of the following is true of the NF1 gene?

- 1- Inherited in a recessive fashion
- 2- Inherited in an X linked fashion
- 3- On chromosome 17
- 4- On mitochondrial genome
- 5- Related to NF2 gene

Answer & Comments

Answer: 3- On chromosome 17

Neurofibromatosis due to NF1 is found on chromosome 17 and is inherited in an autosomal dominant fashion.

NF2 is associated with acoustic neuromas and is found on chromosome 22.

[Q: 3486] OnExamination 2012 - Basic Science

Which of the following organelles contains enzymes responsible for the digestion of constituents of cells and tissues?

- 1- Endoplasmic reticulum
- 2- Golgi apparatus
- 3- Lysosomes
- 4- Microtubules
- 5- Mitochondria

Answer & Comments

Answer: 3- Lysosomes

The lysosomes contain the enzymes and molecules such as oxidases, free radical, etc, responsible for the breakdown of intracellular components.

Microtubules are involved in mitotic processes and intracellular transportation.

The mitochondria produce energy for cellular functions.

[Q: 3487] OnExamination 2012 - Basic Science

Are the following true concerning anti-neutrophilic cytoplasmic autoantibodies?

- 1- ANCA positive glomerulonephritis characteristically causes nephrotic syndrome
- 2- Cause neutropenia in SLE
- 3- Increased in systemic lupus erythematosus (SLE)
- 4- Positive only in Wegener's syndrome associated with renal disease
- 5- Present in inflammatory bowel disease

Answer & Comments

Answer: 5- Present in inflammatory bowel disease

Eighty five percent of untreated subjects with Wegener's will have circulating anti-neutrophil cytoplasmic antibody (cANCA) and those with limited disease are less likely to have positive serology.

Perinuclear anti-neutrophil cytoplasmic antibody (pANCA) is present in approximately 70% with ulcerative colitis and less than 20% of Crohn's patients.

Neither p nor c-ANCA is typical of SLE.

Initial renal damage causes proteinuria (focal proliferative glomerulonephritis) but renal function can deteriorate rapidly with development of acute focal necrotising glomerulonephritis.

[Q: 3488] OnExamination 2012 - Basic Science

A 20-year-old South Asian man presents to the emergency department with a six week history of fever, night sweats and weight loss.

Chest x ray reveals bilateral upper zone cavitory lesions.

What is the next most important investigation?

- 1- CT scan of chest
- 2- HIV test
- 3- Interferon-gamma releasing assay (IGRA)
- 4- Sputum for acid fast bacilli (AFB) examination
- 5- Sputum for M/C&S

Answer & Comments

Answer: 4- Sputum for acid fast bacilli (AFB) examination

Laboratory confirmation enables speciation and susceptibility data to be obtained.

HIV testing should be offered to all patients with TB but is not the next most important investigation.

[Q: 3489] OnExamination 2012 - Basic Science

A 24-year-old female presents with a two day history of a painful swollen erythematous left leg.

On examination, she is confused and hypotensive.

What is the likeliest cause of her infection?

- 1- Group G Streptococcus

- 2- Mixed coliforms and anaerobes
- 3- MRSA
- 4- Clostridium perfringens
- 5- S. pyogenes

Answer & Comments

Answer: 5- S. pyogenes

S. pyogenes (group A Streptococcus) is the likeliest cause.

Mixed coliforms and anaerobes and group G Streptococci occur more commonly in older patients with underlying co-morbidities.

[Q: 3490] OnExamination 2012 - Basic Science

A nurse presents with severe swelling around the mouth following her lunch.

She was treated for suspected anaphylaxis and on further questioning she says that previously she has had an itchy rash on her hands after wearing latex gloves.

Which of the following fruit is the most likely to have been in her lunch to explain this reaction?

- 1- Apple
- 2- Banana
- 3- Gooseberry
- 4- Pineapple
- 5- Star fruit

Answer & Comments

Answer: 2- Banana

"Latex allergy represents an increasing occupational problem, mainly among healthcare workers. An association between latex allergy and hypersensitivity to some plant foods, particularly fruits (the latex-fruit syndrome), has been established. Class I chitinases with an N-terminal hevein-like domain from avocado, chestnut, banana and

other foods, and latex hevein seem to be the allergens responsible for the cross-reactions involved in the latex-fruit syndrome." Salcedo G, Diaz-Perales A, Sanchez-Monge R. The role of plant panallergens in sensitization to natural rubber latex. Curr Opin Allergy Clin Immunol. 2001 Apr;1(2):177-83.

[Q: 3491] OnExamination 2012 - Basic Science

A 45-year-old lady presented with a four month history of malaise, weight loss and, more recently, dyspnoea.

Clinical examination and CXR reveals a pleural effusion and malignancy is suspected as an underlying cause. Tumour markers are requested as part of the workup.

Investigation shows:

CA 15-3 9 U/ml (< 40)

CA 19-9 60 U/ml (< 33)

CA125 620 U/ml (< 35)

Which of the following diagnoses is the most likely?

- 1- Breast cancer
- 2- Hepatoma
- 3- Ovarian fibroma
- 4- Pancreatic cancer
- 5- Small cell lung cancer

Answer & Comments

Answer: 3- Ovarian fibroma

The combination of raised CA 125, pleural effusion and history suggestive of malignancy makes the diagnosis of ovarian fibroma and Meig's disease the most likely of those listed.

CA 15-3 is a tumour marker for breast cancer.

CA- 19-9 is a pancreatic cancer marker.

[Q: 3492] OnExamination 2012 - Basic Science

A 52-year-old man enquired about the advisability of vaccination prior to a holiday abroad.

He had been treated for asthma with long term steroids and regularly required doses of prednisolone in excess of 30 mg daily to control acute exacerbations.

Which one of the following vaccinations would be contraindicated in this man?

- 1- Bacillus Calmette-Guérin - BCG
- 2- Diphtheria toxoid
- 3- H. influenzae B
- 4- Meningococcus
- 5- Tetanus toxoid

Answer & Comments

Answer: 1- Bacillus Calmette-Guérin - BCG

Some individuals, particularly those that are immunosuppressed, are at risk if they are given live vaccines.

Inactivated vaccines are generally not dangerous but may be ineffective.

They are also at risk of severe manifestations to vaccines such as disseminated infection with bacillus Calmette-Guérin (BCG).

Those patients who receive prednisolone 40 mg/day for more than a week or who are on lower doses for more prolonged periods should be considered to be immunosuppressed.

Asthma alone is not a contraindication to vaccination even if patients are taking inhaled corticosteroids.

[Q: 3493] OnExamination 2012 - Basic Science

A 47-year-old woman presents with high fever, rigors and myalgia.

Nasal aspirate is positive for influenza virions.

Which of the following is true of her B cell response?

- 1- Affinity maturation takes place in the blood stream
- 2- Deficiency of either CD40 or CD40L still allows an IgG response
- 3- Her B cells express immunoglobulin on their surface
- 4- Memory cells are not formed as repeated infections with influenza often occur
- 5- The antibody response to the virus does not require T cell help

Answer & Comments

Answer: 3- Her B cells express immunoglobulin on their surface

B cells usually require T cell help for full activation.

B cells activated in the primary immune response initially produce IgM. With continuing T cell help B cells then undergo heavy chain class switching and enter germinal centres in secondary lymphoid organs. The germinal centres are the sites of immunoglobulin affinity maturation and memory B cell formation.

Various factors including the nature of T cell help, antigen exposure site and cytokine profile, determine the isotype of heavy chain produced.

CD40 and CD40L are required for co-stimulation by T cells. Deficiency of either CD40 or CD40L impairs class switching.

Certain antigens can activate B cells in the absence of T cell help - thymus independent antigen. T cell independent B cell responses are mainly to carbohydrate antigen, for example, pneumococcal polysaccharide. These antigens are not processed and presented in association with MHC molecules, and therefore cannot activate T helper cells.

Most TI antigens have highly repetitive epitopes (for example, LPS/endotoxin), which are able to cross link B cell surface immunoglobulin and activate these cells.

Some T cell independent antigens can cause proliferation of B cells regardless of their specificity - polyclonal B cell activation. B cell responses to T independent antigens consist mainly of IgM antibodies of low affinity without the production of memory cells.

The influenza virus will activate T and B cells, and result in memory cell production.

Genetic mutation in the virus is responsible for immune evasion and repeated infections.

[Q: 3494] OnExamination 2012 - Basic Science

A 53-year-old woman presents with a six month history of recurrent facial and tongue swelling.

She associated the attacks with consuming certain food additives and with contact with some cosmetics and cleaning fluids. Her only regular medication was hormone replacement therapy.

Investigations reveal:

Total serum IgE 145 kU/L (0-120)

Serum C₃ 105 mg/dL (65-190)

Serum C₄ 35 mg/dL (15-50)

What is the most likely diagnosis?

- 1- C1 esterase inhibitor deficiency
- 2- Chemical intolerance
- 3- Food allergy
- 4- Idiopathic angio-oedema
- 5- Mastocytosis

Answer & Comments

Answer: 3- Food allergy

The history suggests atopy which is confirmed by the mildly elevated IgE concentration and normal C₄ and C₃ concentrations.

Hereditary or acquired angio-oedema is unlikely given the normal C₄ and the history occurs late. Also the patient herself has noticed a link with food - food allergy is usually easier to diagnose in adults.

The cosmetics (chemical intolerance) are unlikely and the clinical history does not fit mastocytosis.

[Q: 3495] OnExamination 2012 - Basic Science

Which of the following is a typical feature of farmer's lung?

- 1- Basal crackles
- 2- Eosinophilia
- 3- Haemoptysis
- 4- Increased pCO₂
- 5- Positive serum paraproteins

Answer & Comments

Answer: 1- Basal crackles

Farmer's lung is the commonest occupational extrinsic allergic alveolitis, due to thermophilic actinomycetes.

Crackles are typically heard at the bases. Other signs depend on the stage of disease.

In the acute form, the symptoms usually start 4- hours after exposure to the sensitising antigen. There is malaise, fever, chest tightness, dry cough, and dyspnoea. Signs include tachypnoea and bibasal fine inspiratory crackles; wheeze is rare. Life-threatening respiratory failure can develop.

In the subacute form, symptoms are less severe and include a productive cough, dyspnoea, fatigue, anorexia and weight loss. There are often recurrent attacks, which may present as pneumonia. After the exposure is

removed it can take weeks or months for the symptoms to resolve.

In the chronic form there are minimal systemic symptoms, but marked limitation of exercise tolerance due to dyspnoea. If the source of the antigen is removed there is usually only partial improvement of symptoms. Cyanosis, cludding and inspiratory crackles over the lower lung fields may be present. Eventually chronic hypoxia and pulmonary hypertension with right heart failure develop. There may be acute exacerbations.

Eosinophilia can be seen but is not typical.

Immunoglobulin levels are frequently elevated but not a paraprotein.

P02 may be decreased particularly with exercise.

A restrictive pattern on LF studies is seen.

[Q: 3496] OnExamination 2012 - Basic Science

Which one of the following statements concerning T lymphocytes is correct?

- 1- Are infected by Epstein-Barr virus in infectious mononucleosis
- 2- Are the primary host response in bacterial infection
- 3- Compose the majority of lymphocytes in plasma
- 4- Produce IgG
- 5- T cell lymphoma has a better prognosis than B cell lymphoma

Answer & Comments

Answer: 3- Compose the majority of lymphocytes in plasma

The primary host response to bacterial infections is dependent on mononuclear phagocytes and neutrophils.

T lymphocytes are involved in cell-mediated acquired immune responses, whereas B lymphocytes are involved in humoral immunity and produce immunoglobulins.

T lymphocytes compose the majority of circulating lymphocytes in plasma.

Epstein-Barr virus infects B lymphocytes and squamous epithelial cells of the oropharynx. The virus can transform B cells and epithelial cells to produce Burkitt's lymphoma, a subset of Hodgkin's lymphoma, nasopharyngeal carcinoma and oral hairy leukoplakia.

T cell lymphoma makes up about 10-20% of non-Hodgkin's lymphomas and has a worse prognosis than B cell lymphoma.

[Q: 3497] OnExamination 2012 - Basic Science

A 24-year-old pregnant female delivers at term by normal vaginal delivery.

Antenatal screening for hepatitis B had revealed the following results:

Hepatitis B core Ab positive

Hepatitis B surface Ag positive

Hepatitis BeAg negative

What are the most appropriate measures to reduce the risk of mother to child transmission?

- 1- Accelerated hepatitis B immunisation at 0,1,2 and 12 months
- 2- Accelerated hepatitis B immunisation and hepatitis B immunoglobulin
- 3- Advise against breast feeding
- 4- Hepatitis B immunisation at 0,1 and 6 months
- 5- Offer reassurance

Answer & Comments

Answer: 1- Accelerated hepatitis B immunisation at 0,1,2 and 12 months

Accelerated hepatitis B immunisation is preferable to routine immunisation to prevent neonatal infection.

Hepatitis B immunoglobulin should also be administered only if the neonate has a low birth weight or the mother is a chronic carrier of high infectivity (hepatitis B eAg positive).

Advising against breast feeding does not reduce the risk of neonatal infection.

[Q: 3498] OnExamination 2012 - Basic Science

A 75-year-old man has a history of chronic lymphocytic leukaemia. He has had treatment with several courses of chemotherapy and has now been admitted to hospital with pneumonia.

His medical history revealed that he had suffered several previous upper respiratory tract infections over the previous six months.

Which of the following components of his immune system is likely to be deficient?

- 1- Complement
- 2- Immunoglobulin G
- 3- Macrophages
- 4- Mast cells
- 5- T lymphocytes

Answer & Comments

Answer: 2- Immunoglobulin G

Chronic lymphocytic leukaemia (CLL) is commonly complicated by panhypogammaglobulinaemia.

Although intravenous immunoglobulin prevents recurrent infections it does not prolong survival.

[Q: 3499] OnExamination 2012 - Basic Science

A 25-year-old sexually active Afro-Caribbean

female presents with a non-traumatic swollen left knee.

A knee aspirate reveals numerous polymorphs and gram negative diplococci.

What is the likeliest cause of infection?

- 1- H. influenzae
- 2- N. gonorrhoeae
- 3- N. meningitidis
- 4- S. aureus
- 5- S. pyogenes

Answer & Comments

Answer: 2- N. gonorrhoeae

Although all the above organisms may cause septic arthritis, only Neisseria species are gram-negative diplococci.

Given the above clinical scenario, the likeliest cause is gonorrhoea rather than meningococcal disease.

[Q: 3500] OnExamination 2012 - Basic Science

A 34-year-old female is admitted to hospital with neutropenic sepsis following recent chemotherapy for acute myeloid leukaemia. Cultures are taken and she is commenced on intravenous tazobactam/piperacillin and gentamicin.

Five days later her fever is still persisting and a chest x ray reveals patchy infiltrates throughout both lung fields.

What is the likeliest diagnosis?

- 1- Hospital-acquired bacterial pneumonia
- 2- Influenza
- 3- Invasive aspergillosis
- 4- PCP
- 5- Pulmonary TB

Answer & Comments

Answer: 3- Invasive aspergillosis

Most neutropenic sepsis protocols recommend the addition of an antifungal agent, generally liposomal amphotericin B, to empirical antibacterial treatment after three days to cover this possibility.

[Q: 3501] OnExamination 2012 - Basic Science

A healthcare worker sustained a needle stick injury from a known HIV seropositive patient not taking antiretroviral therapy.

Assuming the healthcare worker is HIV seronegative, what is the risk of transmission?

- 1- 1/3
- 2- 1/30
- 3- 1/300
- 4- 1/3000
- 5- 1/30000

Answer & Comments

Answer: 3- 1/300

This is an estimated risk based on retrospective case-control studies.

Evaluating risk is important when counselling a patient and deciding when to offer post-exposure prophylaxis.

[Q: 3502] OnExamination 2012 - Basic Science

A 62-year-old man who has recently had his medication for hypertension altered presents with flushing, stridor, shortness of breath and hypotension.

He comes to the emergency department and receives intravenous hydrocortisone, intramuscular adrenaline, and intravenous antihistamine. After a slow recovery he is

discharged home for planned review at the allergy clinic.

Which of the following medications is most likely to be responsible for his presentation?

- 1- Amlodipine
- 2- Atenolol
- 3- Bendroflumethiazide
- 4- Doxazosin
- 5- Ramipril

Answer & Comments

Answer: 5- Ramipril

This man has presented with anaphylaxis.

Whilst angio-oedema may be hereditary or idiopathic, it is also associated with use of both ACE inhibitors and angiotensin receptor blockers (ARB). Given that he has recently increased his anti-hypertensive medication, presentation with angio-oedema associated with ACE inhibitor therapy seems the most likely explanation.

He should cease ramipril therapy and not commence either ACE inhibitors or ARBs in the future.

[Q: 3503] OnExamination 2012 - Basic Science

A 24-year-old nurse is admitted to the Emergency department with symptoms of anaphylaxis. She is known to be allergic to latex and collapsed whilst having a fruit salad for her lunch with colleagues. You suspect that she has the latex fruit syndrome.

On examination her BP is 95/60 mmHg and her pulse is 105. She has audible stridor and a very flushed facial appearance. She responds to treatment with IV hydrocortisone, nebulised salbutamol and s/c adrenaline.

Which of the following inflammatory mediators is thought to be important in anaphylaxis?

- 1- IL1
- 2- IL2
- 3- IL4
- 4- IL6
- 5- IL10

Answer & Comments

Answer: 3- IL4

Mediators involved in the development of anaphylaxis include histamine, leukotrienes, prostaglandins and platelet aggregating factor, which are generated by mast cell degranulation.

Additional factors include

Tryptase

Chimase

Heparin

Chondroitin sulphate

IL4

IL13.

IL4 and IL13 are thought to be important in driving the onward cascade of inflammation to other immune system cells and contribute to the severity of anaphylaxis.

[Q: 3504] OnExamination 2012 - Basic Science

Class I major histocompatibility complexes (MHCs) react with which of the following on T cells to result in immune system activation?

- 1- CD 1
- 2- CD 2
- 3- CD 5
- 4- CD 8
- 5- CD 10

Answer & Comments

Answer: 4- CD 8

Proteins are displayed on the cell surface by MHC I human leukocyte antigen (HLA) antigens.

If the MHC I is presenting material recognised as foreign, then it is detected and destroyed by CD 8 plus T cells.

[Q: 3505] OnExamination 2012 - Basic Science

Class II major histocompatibility complexes (MHCs) are present on which of the following cells?

- 1- B cells
- 2- Erythrocytes
- 3- Natural killer cells
- 4- Platelets
- 5- Resting T cells

Answer & Comments

Answer: 1- B cells

Class II MHCs are present on all antigen presenting cells, for example,

B cells

Dendritic cells

Macrophages

Langerhans cells.

They are also present on activated T cells.

[Q: 3506] OnExamination 2012 - Basic Science

The Mantoux reaction is an example of which type of hypersensitivity reaction?

- 1- Humoral immune response
- 2- Type I hypersensitivity
- 3- Type II hypersensitivity

- 4- Type III hypersensitivity
- 5- Type IV hypersensitivity

Answer & Comments

Answer: 5- Type IV hypersensitivity

The tuberculin skin test is an example of a type IV hypersensitivity or a delayed type hypersensitivity (DTH) reaction. This reaction develops when primed Th1 cells encounter their specific antigen. An inflammatory response evolves over 24-72 hours.

In the tuberculin skin test the injected antigen is protein derived from *M. tuberculosis*. Th1 cells recognise peptide bound to major histocompatibility complex on APCs and are activated to secrete pro-inflammatory cytokines including interleukin-2 (IL2), interferon (IFN)-gamma, tumour necrosis factor (TNF), chemokines and granulocyte-macrophage colony-stimulating factor (GM-CSF).

There is recruitment of inflammatory cells, predominantly macrophages, to the site of antigen deposition with activation of phagocytes.

Some cytokines (TNF) as well as macrophage derived lytic enzymes cause local tissue destruction. CD8+ T-cells have also been implicated in DTH responses. The result is an indurated erythematous lesion at the site of injection which indicates previous exposure to TB.

[Q: 3507] OnExamination 2012 - Basic Science

Are the following true regarding leukotrienes?

- 1- Are formed from the cyclo-oxygenase pathway
- 2- Are synthesised by fibroblasts
- 3- Decrease vascular permeability

- 4- Leukotriene D4 has been identified as SRS-A which causes bronchial wall smooth muscle relaxation
- 5- Stimulate mucus secretion

Answer & Comments

Answer: 5- Stimulate mucus secretion

Leukotrienes are synthesised by leucocytes.

They are mediators of allergic reaction.

They increase vascular permeability and attract neutrophils and eosinophils to inflammatory sites.

Leukotrienes are synthesised via the lipoxygenase pathway.

Leukotriene D4 has been identified as SRS-A which causes bronchial wall and intestinal smooth muscle contraction (not dilatation).

Leukotrienes also stimulate mucus production, an important consideration in the pathophysiology of bronchial asthma.

[Q: 3508] OnExamination 2012 - Basic Science

A healthcare worker sustained a needle stick injury from a known hepatitis B chronic carrier of high infectivity.

Assuming the healthcare worker is susceptible to hepatitis B, what is the risk of transmission?

- 1- 1/3
- 2- 1/30
- 3- 1/300
- 4- 1/3000
- 5- 1/30000

Answer & Comments

Answer: 1- 1/3

This is an estimated risk based on retrospective case-control studies.

Evaluating risk is important when counselling a patient.

The patient should be offered hepatitis B immunoglobulin and an accelerated course of hepatitis B vaccine.

[Q: 3509] OnExamination 2012 - Basic Science

Which of the following is true regarding the genetics of bronchial asthma?

- 1- Genetic linkage is to a single chromosome 13
- 2- Leukotriene concentrations are influenced by genetic factors
- 3- Mendelian recessive inheritance
- 4- Similar concordance in monozygotic and dizygotic twins
- 5- There is a contribution from HLA alleles

Answer & Comments

Answer: 5- There is a contribution from HLA alleles

There may be genetic linkage of atopic trait to chromosome 11, with association between response to antigen and HLA haplotype.

IgE concentrations are influenced by genetic factors.

[Q: 3510] OnExamination 2012 - Basic Science

A 43-year-old United Kingdom born HIV seropositive patient is admitted to hospital with a three week history of fever, weight loss and night sweats. He had been non-compliant with his antiretroviral therapy.

On admission CD4 count was $35 \times 10^6/l$ and CXR normal.

What is the likeliest cause of his fevers?

- 1- Cryptococcus neoformans
- 2- Mycobacterium avium

- 3- Mycobacterium tuberculosis
- 4- Salmonella enteritidis
- 5- Streptococcus pneumoniae

Answer & Comments

Answer: 2- Mycobacterium avium

As the CD4 count is less than $100 \times 10^6/l$, this is a typical presentation for disseminated Mycobacterium avium infection.

Mycobacterium tuberculosis is possible but less likely as the patient is UK born and CXR normal.

Streptococcus pneumoniae is likely to present as an acute respiratory illness and Cryptococcus neoformans as meningitis.

Salmonella enteritidis is possible but less likely than disseminated Mycobacterium avium infection.

[Q: 3511] OnExamination 2012 - Basic Science

A 45-year-old female presents with symptoms and signs suggestive of a pyelonephritis.

A MSU reveals +++ WBCs and a heavy growth of an extended spectrum beta-lactamase (ESBL) producing Escherichia coli is isolated.

What is the most appropriate treatment?

- 1- Amoxicillin
- 2- Ciprofloxacin
- 3- Co-amoxiclav
- 4- Imipenem
- 5- Trimethoprim

Answer & Comments

Answer: 4- Imipenem

An ESBL is an enzyme that inactivates most beta-lactamase antibiotics.

These organisms are often resistant to other antibiotics such as trimethoprim and ciprofloxacin.

Beta-lactam/beta-lactam inhibitor combinations such as co-amoxiclav may have some activity but are unreliable when used to treat severe infections.

[Q: 3512] OnExamination 2012 - Basic Science

Which one of the following is correct concerning mast cells?

- 1- Are lipophilic cells involved in inflammatory and immune responses
- 2- Cross-linkage of surface IgA molecules by antigen may cause an anaphylactic reaction
- 3- Degranulation releases lytic enzymes and inflammatory mediators from storage granules
- 4- Depletion of circulating mast cells can cause mastocytosis
- 5- Do not contain heparin

Answer & Comments

Answer: 3- Degranulation releases lytic enzymes and inflammatory mediators from storage granules

Mast cells are basophilic cells in the connective and subcutaneous tissues, which are involved in inflammatory and immune responses.

They contain storage granules that contain lytic enzymes (for example, tryptase) and inflammatory mediators, for example:

Histamine

Heparin

5-Tryptase hydroxytryptamine (5-HT)

Leukotrienes

Platelet aggregating factor

Leukocyte chemotactic factor

Hyaluronidase.

Release of these mediators occurs during mast cell degranulation, which can be triggered by:

Tissue injury

Drugs

Complement activation

Foreign antigenic material.

An anaphylactic reaction occurs when a previously sensitised individual is re-exposed to the antigen. It is an IgE mediated immune response.

Mastocytosis occurs when excess mast cells are present in the circulation or as tissue infiltrates.

[Q: 3513] OnExamination 2012 - Basic Science

A 22-year-old female develops a wheeze and extensive rash whilst eating a Chinese take-away.

On examination, she has extensive wheeze and stridor, with urticaria covering her upper and lower limbs and trunk. Her BP is 80/45 mmHg.

What is the likely diagnosis?

- 1- C1 esterase deficiency
- 2- Food poisoning
- 3- Idiopathic urticaria
- 4- Monosodium glutamate syndrome
- 5- Peanut allergy

Answer & Comments

Answer: 5- Peanut allergy

Chinese cooking uses cashew nuts in many dishes, and patients with peanut allergy may also experience an anaphylactic reaction with cashew nuts. Chinese chefs also use peanut oil

in the stir fry, and this may also precipitate an allergic reaction.

An acute hypersensitivity reaction to monosodium glutamate (MSG) a flavour enhancer common in Chinese food, may give rise to the 'MSG syndrome'. This is characterised by

A sudden onset of headache

Heartburn

Palpitations

Sweating

Swelling

Flushing of the face.

Patients may report a sense of increased facial pressure or tingling in the face. Symptoms generally start within two hours of eating foods rich in MSG. This condition is generally self-limited and will resolve. Antihistamines can be helpful in some cases.

It is extremely unlikely that this syndrome will cause shock, which is what this patient presents with given the hypotension.

[Q: 3514] OnExamination 2012 - Basic Science

Which of the following statements regarding B-type natriuretic peptide (BNP) is correct?

- 1- BNP augments sodium reabsorption in the kidney
- 2- BNP causes arterial and venous smooth muscle vasodilatation
- 3- BNP is synthesised predominantly in the cerebrovascular circulation
- 4- BNP synthesis is decreased by thyroid hormone
- 5- The stimulus for BNP release is increased ventricular pressure load

Answer & Comments

Answer: 2- BNP causes arterial and venous smooth muscle vasodilatation

The ventricular myocardium is the primary site of BNP synthesis.

The stimulus for BNP release is myocyte stretch, rather than transmural pressure load.

BNP synthesis is increased by thyroid hormones as well as glucocorticoids, endothelin-1, angiotensin-II and tachycardia, independent of the haemodynamic effects of these factors.

In the kidney, BNP causes increased glomerular filtration rate (GFR) and inhibition of sodium reabsorption, leading to natriuresis and diuresis.

BNP leads to reduced blood pressure, and reduced pre-load due to relaxing effects on vascular smooth muscle.

For an informative review refer to Lancet 2003;362:316-22.

[Q: 3515] OnExamination 2012 - Basic Science

A 55-year-old nurse developed bronchospasm and urticaria twenty minutes into surgery under general anaesthesia.

The mast cell tryptase concentration confirmed an acute allergic reaction.

Later, it transpired that she had developed allergic reactions at her dentist and had developed frequent episodes of wheezing when assisting at sterile procedures.

What is the most likely diagnosis?

- 1- Allergy to anaesthetic induction agents
- 2- Allergy to local anaesthetic agents
- 3- Latex allergy
- 4- Pressure urticaria
- 5- Systemic mastocytosis

Answer & Comments

Answer: 3- Latex allergy

This patient developed anaphylaxis during a surgical procedure and it appears that she had problems with allergies during dental treatment and whilst assisting during sterile procedures.

This would suggest that she is allergic to latex rather than induction agents or local anaesthesia as latex would be present in all three of the above procedures.

Systemic mastocytosis is a disease which usually affects the elderly and is associated with:

Urticaria pigmentosa

Diarrhoea

Hypotension

Sclerotic bone changes and

Mast cell infiltration of organs such as spleen, liver and kidneys.

[Q: 3516] OnExamination 2012 - Basic Science

Which of the following statements is true of xenotransplantation?

- 1- Has not yet been performed in humans
- 2- Is characterised by a vigorous early cell-mediated immune response
- 3- Is the transfer of organs between species
- 4- Is the transfer of tissue grown in-vitro
- 5- Requires a close HLA match

Answer & Comments

Answer: 3- Is the transfer of organs between species

Xenotransplantation is the transfer of organs between species - particularly the transfer of animal organs to humans. Compare this with

allotransplantation which is the transfer of organs within the same species.

There have already been several documented cases of xenotransplantation - baboon heart, chimpanzee kidneys.

A close human leukocyte antigen (HLA) match is not possible of course, unless a transgenic species is used that express human major histocompatibility complexes (HLA).

Early immune response is humoral - immunoglobulin M (IgM).

[Q: 3517] OnExamination 2012 - Basic Science

Which of the following statements concerning the thymus is true?

- 1- A proportion of alpha/beta+ thymocytes undergo isotype switching to produce gamma/delta+ T cells.
- 2- CD4/CD8 double positive cells are eliminated by a process of negative selection.
- 3- Mature thymocytes express surface IgM and IgD.
- 4- The majority of cortical thymocytes express either CD4 or CD8.
- 5- Thymocytes whose TcR bind with high affinity to self Ag/MHC complexes are clonally deleted.

Answer & Comments

Answer: 5- Thymocytes whose TcR bind with high affinity to self Ag/MHC complexes are clonally deleted.

Cortical thymocytes are immature forms, and either do not express CD4 or CD8 (double negative cells) or express both CD4 and CD8 (double positive cells). As the cells mature, they pass to the thymic medulla, where they lose expression of either CD4 or CD8, to become single positive cells.

Negative selection occurs at the stage when thymocytes express both CD4 and CD8, but co-expression of these markers does not mediate negative selection. Negative selection occurs when a thymocyte expresses a TcR with high affinity for self antigen:MHC complexes in the thymic micro-environment.

Once a thymocyte has successfully rearranged and expressed an alpha/beta or gamma/delta TcR it is committed to that lineage.

Thymocytes whose TcR bind with high affinity to self Ag/MHC complexes are clonally deleted by a process of negative selection.

B cells express IgM and IgD; T cells do not.

[Q: 3518] OnExamination 2012 - Basic Science

A 50-year-old African-American woman presents with episodic toe and finger problems characterised by pallor, cyanosis, suffusion and pain of the fingers and toes in response to cold. She later develops difficulty in swallowing and dyspnoea. Inspiratory crackles are heard on auscultation.

Which of the following immunological investigations is the most specific for this lady's condition?

- 1- Anticentromere antibody
- 2- Anti-ds DNA antibody
- 3- Antitopoisomerase I (Scl-70) antibody
- 4- Rheumatoid factor
- 5- Topoisomerase I

Answer & Comments

Answer: 3- Antitopoisomerase I (Scl-70) antibody

This lady has systemic sclerosis as suggested by the:

Dyspnoea (lung fibrosis or pulmonary hypertension)

Dysphagia (oesophageal involvement) and Raynaud's.

Systemic sclerosis is a chronic autoimmune disease characterised by increased fibroblast activity and fibrosis in a number of different organ systems. Ninety to 95% of patients have positive antinuclear antibodies.

There are two major subtypes:

Limited cutaneous and

Diffuse cutaneous.

CREST syndrome is an older term for the limited cutaneous form (calcinosis, Raynaud's phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasia).

Patients with systemic sclerosis can present with skin abnormalities, musculoskeletal changes, gastrointestinal complications, pulmonary disease, renal crisis and dry eyes and mouth.

A number of autoantibodies against extractable nuclear antigens can be detected in patients with systemic sclerosis. Anti-centromere antibodies and anti-topoisomerase I antibodies are the classic autoantibodies associated with the disease. Anti-centromere antibodies are linked with limited cutaneous involvement and isolated pulmonary hypertension, and a good prognosis, whereas anti-topoisomerase I are linked with diffuse skin disease and pulmonary fibrosis and a higher mortality.

Respiratory symptoms are common in patients with systemic sclerosis, but it is often difficult to distinguish between interstitial lung disease and pulmonary hypertension as the cause. Echocardiography, pulmonary hypertension and chest radiographs or CT are often required.

Inspiratory crackles heard here make interstitial lung disease the most likely diagnosis, but it is important to note they are not always present in the early stages of

disease. Signs of pulmonary hypertension are jugular venous distension, right ventricular heave and an accentuated pulmonary second heart sound.

Anti-ds DNA antibodies are characteristic of systemic lupus erythematosus (SLE). Rheumatoid factor is non-specific, but is associated with rheumatoid arthritis. Topoisomerase III is not an investigation which is routinely used.

[Q: 3519] OnExamination 2012 - Basic Science

A healthcare worker sustained a needle stick injury from a known chronic hepatitis C carrier who has not been previously treated.

Assuming the healthcare worker is hepatitis C negative, what is the risk of transmission?

- 1- 1/3
- 2- 1/30
- 3- 1/300
- 4- 1/3000
- 5- 1/30000

Answer & Comments

Answer: 2- 1/30

This is an estimated risk based on retrospective case-control studies.

Evaluating risk is important when counselling a patient and deciding when to offer post-exposure prophylaxis.

[Q: 3520] OnExamination 2012 - Basic Science

Which of the following cell types have a prime role in recognising and destroying virus infected cells in an HLA class I-restricted manner?

- 1- B cells
- 2- CD8+ T lymphocytes

- 3- Dendritic cells
- 4- Macrophages
- 5- Platelets

Answer & Comments

Answer: 2- CD8+ T lymphocytes

CD8+ T lymphocytes are otherwise known as cytotoxic T lymphocytes.

The T cell receptor on the surface of the CD8+ T cell recognises virus peptides in the context of self HLA class I molecules on the surface of virus infected antigen presenting cells. The infected cell is then lysed.

Dendritic cells are professional antigen presenting cells presenting antigen to CD4+ helper cells and CD8+ T cells, but have no cytotoxic potential.

B cells produce antibodies.

Macrophages are also antigen presenting cells but are also involved in recognition and eradication of certain intracellular pathogens but in a non-HLA restricted manner.

[Q: 3521] OnExamination 2012 - Basic Science

A 45-year old UK born male presents with a swollen left knee two months after an arthroscopy.

A knee aspirate reveals ++PCs and ++ Gram positive cocci in clumps.

What is the likeliest cause of infection?

- 1- H. influenzae
- 2- N. gonorrhoeae
- 3- N. meningitidis
- 4- S. aureus
- 5- S. pyogenes

Answer & Comments

Answer: 4- S. aureus

Although all the above organisms may cause septic arthritis, only *S. aureus* and *S. pyogenes* could cause septic arthritis post procedure.

S. aureus is a far commoner cause than *S. pyogenes*.

[Q: 3522] OnExamination 2012 - Basic Science

A 65-year-old smoker presents to a respiratory clinic with a four week history of cough and weight loss.

CXR appears normal. *Mycobacterium avium* is cultured from a sputum sample.

What is the next appropriate investigation?

- 1- Bronchoscopy
- 2- CT scan of chest
- 3- Interferon-gamma releasing assay
- 4- Sputum for AFB examination
- 5- Sputum for M/C&S

Answer & Comments

Answer: 5- Sputum for M/C&S

To diagnose pulmonary *Mycobacterium avium* infection with confidence, attempts should be made to culture the organism from repeated sputum samples.

A CT scan is the next most important investigation as this may reveal pulmonary infiltrates despite a normal CXR.

[Q: 3523] OnExamination 2012 - Basic Science

Which of the following statements is true about immunological reactions?

- 1- Angioneurotic oedema is the most severe form of type I reaction
- 2- Deficiencies in the terminal components of complement increase the risk of meningococcal disease

- 3- Graves' disease is caused by a type IV reaction
- 4- Serum sickness is caused by a type II reaction
- 5- Urticaria usually responds to cimetidine

Answer & Comments

Answer: 2- Deficiencies in the terminal components of complement increase the risk of meningococcal disease

Serum sickness is due to circulating antibody-antigen complexes (type III).

Graves' disease is due to stimulating antibody (type V).

The most severe variety of type I reaction is anaphylaxis, with angio-oedema an intermediate reaction associated with wheeze and swelling of the lips and severe urticaria. These reactions are mediated by histamine 1 receptor stimulation.

Congenital C1 inhibitor deficiency is also caused by hereditary angio-oedema. Deficiencies in C1r, s, and 2-4 result in vasculitides; while deficiencies in C2, 3 and 5-8 are associated with an increased risk of septicaemia.

[Q: 3524] OnExamination 2012 - Basic Science

A 16-year-old female develops an urticarial reaction and is suspected of peanut allergy yet measurement of peanut-specific IgE antibodies on RAST testing is within the normal range.

Which of the following would be the next most appropriate investigation?

- 1- C1 esterase concentrations
- 2- Food provocation testing
- 3- Mast cell degranulation testing
- 4- No other test necessary diagnosis can be secured on history

5- Skin prick testing

Answer & Comments

Answer: 5- Skin prick testing

The most appropriate next test would be skin allergen testing as a food provocation test is often unnecessary and can prove rather dangerous although it is the gold standard.

[Q: 3525] OnExamination 2012 - Basic Science

A 37-year-old woman underwent a kidney transplant which never functioned.

A biopsy revealed pathological features consistent with acute rejection associated with anti-HLA antibodies.

Which type of immunoglobulin is expected to account for this process?

- 1- Ig A
- 2- Ig D
- 3- Ig E
- 4- Ig G
- 5- Ig M

Answer & Comments

Answer: 4- Ig G

This acute rejection is recognised and due to anti-IgG antibodies to the human leukocyte antigen (HLA) incompatible tissues with primary activation of T cells.

The acute response is treated with immunosuppressants.

[Q: 3526] OnExamination 2012 - Basic Science

A 51-year-old man presents with wheals and urticaria. He takes a variety of medications.

Which drug is the most likely to have caused this reaction?

- 1- Aspirin
- 2- Glyceryl trinitrate
- 3- Omeprazole
- 4- Paracetamol
- 5- Simvastatin

Answer & Comments

Answer: 1- Aspirin

The most likely cause of an urticarial eruption from this list would be aspirin.

Other drugs frequently associated with urticaria include

Non-steroidal anti-inflammatory drugs (NSAIDs)

Penicillin

Angiotensin-converting enzyme (ACE) inhibitors

Thiazides

Codeine.

[Q: 3527] OnExamination 2012 - Basic Science

Which of the following statements regarding the genetic and immunological basis of coeliac disease is correct?

- 1- 50% of patients are HLA-DQ 2 or HLA-DQ 8 positive
- 2- Alpha-gliadin specific CD8 cells can be identified in the intestinal wall of untreated patients with coeliac disease
- 3- Cow's milk proteins may precipitate an immune-related enteropathy indistinguishable from coeliac disease
- 4- Tissue transglutaminase generates the antigenic epitopes present in alpha-gliadin
- 5- TNF-alpha plays a critical role in the inflammatory response in the intestinal wall of patients with untreated coeliac disease

Answer & Comments

Answer: 4- Tissue transglutaminase generates the antigenic epitopes present in alpha-gliadin

The prevalence of coeliac disease is 1% in western societies, and is thus one of the commonest immune-mediated diseases.

It arises as a result of genetic predisposition, at least 95% of patients are HLA-DQ2 or HLA-DQ8 positive, and also from the specific immune response to the alpha-gliadin component of gluten.

Cow's milk can produce an immunologically mediated enteropathy, but the condition is rare and transient.

The action of tissue transglutaminase on alpha-gliadin generates epitopes to CD4+ T lymphocytes, which provoke an inflammatory response in the intestinal wall.

In untreated individuals, alpha-gliadin specific CD4+ T cells can be found producing interferon-gamma in the intestinal wall.

[Q: 3528] OnExamination 2012 - Basic Science

Which of the following concerning IgG is correct?

- 1- It has a molecular weight of 50,000 kd.
- 2- It is monovalent.
- 3- It comprises the majority of circulating antibody in serum.
- 4- It differs from other isotypes in not being able to cross the placental barrier.
- 5- It is the major antibody produced during the primary response.

Answer & Comments

Answer: 3- It comprises the majority of circulating antibody in serum.

A. Each light chain has a MW of 25,000 and each H chain a MW of 50,000. Therefore, since

the whole molecule consists of 2 L and 2 H chains, the MW is 150,000 kd.

B. It exists as a monomer with 2 Fab portions, each of which can interact with an antigenic determinant. Therefore it is divalent.

C. Normal range 8-19 g/l. Next is IgA, 1-5 g/l, followed by IgM 0.5- 2 g/l.

D. It is in fact the only antibody capable of crossing the placental barrier, which it does through gaining attachment via its Fc portion.

E. It is the major antibody produced in the secondary immune response. IgM is the major antibody produced during the primary response.

[Q: 3529] OnExamination 2012 - Basic Science

Which molecule is produced in the nucleus, matures in the cytoplasm, binds to the ribosome and initiates protein synthesis?

- 1- Messenger RNA
- 2- Ribosomal RNA
- 3- RNA nucleotide
- 4- RNA polymerase
- 5- Transfer RNA

Answer & Comments

Answer: 1- Messenger RNA

Protein synthesis consists of two phases.

Transcription is where one strand of the deoxyribonucleic acid (DNA) double helix is used as a template by ribonucleic acid (RNA) polymerase to synthesise messenger RNA from RNA nucleotides.

The mRNA then migrates into the cytoplasm maturing, for example, by the splicing of non-coding sequences.

Translation occurs when the ribosome binds to mRNA at the start codon and transfer RNA brings amino acids into position along the

mRNA template. Ribosomal RNA interacts with transfer RNA during translation by providing peptidyl transferase activity.

The ribosome moves from codon to codon along the mRNA producing a polypeptide sequence.

Each type of RNA consists of nucleotides, which are made up of phosphate, ribose sugar and nitrogen bases.

RNA polymerase is the enzyme which is responsible for synthesizing RNA molecules.

[Q: 3530] OnExamination 2012 - Basic Science

Where does RNA splicing occur?

- 1- Cytoplasm
- 2- Endoplasmic reticulum
- 3- Mitochondria
- 4- Nucleus
- 5- Ribosome

Answer & Comments

Answer: 4- Nucleus

Coding sequence is interrupted by non-coding sequences.

Removal of the introns in RNA transcript modification is called RNA splicing.

Splicing occurs in the nucleus before transport to the cytoplasm.

Exons are expressed sequences: these sequences are those present in mature mRNA.

[Q: 3531] OnExamination 2012 - Basic Science

Which of the following are found in eukaryotic and prokaryotic cells?

- 1- Chromosomes

- 2- Introns
- 3- Linear DNA
- 4- Nuclear membrane
- 5- Ribosomes

Answer & Comments

Answer: 5- Ribosomes

Eukaryotes (higher organisms) have multiple chromosomes in the genome which is separated from the rest of the cell by nuclear membranes.

Prokaryotes lack a membrane bound nucleus, and their DNA occurs in a circular form.

Transcription of eukaryotic genes requires non-coding sequences (introns) in the mRNA to be spliced out before translation at the ribosome.

Both eukaryotes and prokaryotes have a ribosome, though the ribosome is significantly larger in eukaryotes.

[Q: 3532] OnExamination 2012 - Basic Science

In which one of the following conditions is deoxyribonucleic acid (DNA) analysis the most useful diagnostic test?

- 1- Adult polycystic kidney disease
- 2- Down's syndrome
- 3- Huntington's chorea
- 4- Hypertrophic obstructive cardiomyopathy
- 5- Klinefelter's syndrome

Answer & Comments

Answer: 3- Huntington's chorea

Klinefelter's syndrome and Down's syndrome are diagnosed principally by chromosomal analysis/karyotype - XXY in the former and trisomy C21 or translocation in the latter.

A trinucleotide CAG repeat expansion in the Huntington gene is diagnostic of Huntington disease.

The majority of cases of hypertrophic cardiomyopathy (HOCM) are autosomal dominantly inherited yet defective genes are located on a variety of chromosomes.

DNA linkage analysis is used to assist in the diagnosis of adult polycystic kidney disease (PKD) but the presence of multiple copies continues to complicate the development of reagents for direct genetic testing, at least of the 70% of PKD1 that is replicated elsewhere.

[Q: 3533] OnExamination 2012 - Basic Science

Which one of the following has its own self-replicating DNA?

- 1- Golgi body
- 2- Lysosomes
- 3- Mitochondria
- 4- Peroxisome
- 5- Rough endoplasmic reticulum

Answer & Comments

Answer: 3- Mitochondria

Abnormalities of mitochondrial deoxyribonucleic acid (DNA) are associated with

Inherited conditions such as Leber's optic atrophy

Mitochondrial myopathy

Lactic acidosis and stroke-like episodes (MELAS) syndrome, and

Diabetes insipidus, diabetes mellitus, optic atrophy and deafness (DIDMOAD).

[Q: 3534] OnExamination 2012 - Basic Science

Transcription RNA (tRNA) has three bases specific for a particular amino acid with which it binds to messenger RNA (mRNA).

Which of the following is this specific area of tRNA?

- 1- Anticodon
- 2- Codon
- 3- Exon
- 4- Intron
- 5- Transposon

Answer & Comments

Answer: 1- Anticodon

mRNA has codons which are bound by the anticodons on tRNA during translation of protein synthesis.

Exons are coding sequences in the mRNA and introns are areas of unknown function.

Transposons are genetic sequences that have been transposed from one part of DNA to another.

[Q: 3535] OnExamination 2012 - Basic Science

Which of the following is true of restriction enzymes?

- 1- Are involved in cell cycle arrest
- 2- Cut DNA
- 3- Degrade DNA
- 4- Join two pieces of DNA together
- 5- Synthesise DNA

Answer & Comments

Answer: 2- Cut DNA

Restriction enzymes cut deoxyribonucleic acid (DNA) at sequences specific for each

restriction enzyme; they are vital tools for molecular biology and molecular genetic research.

[Q: 3536] OnExamination 2012 - Basic Science

Which of the following is true regarding proteins known as cyclins?

- 1- Are differentially expressed throughout the cell cycle
- 2- Regulate antibody production
- 3- Regulate DNA transcription
- 4- Regulate the cycling of receptors between the cell surface and the cytoplasm
- 5- Regulate the menstrual cycle

Answer & Comments

Answer: 1- Are differentially expressed throughout the cell cycle

Cyclins are key regulators of the cell cycle; different cyclins are expressed at different stages of the cell cycle.

[Q: 3537] OnExamination 2012 - Basic Science

The level of cellular telomerase activity will affect which of the following?

- 1- Cell death
- 2- Cell survival
- 3- RNA synthesis
- 4- The number of cell divisions a cell is capable of undergoing
- 5- The rate of cell growth

Answer & Comments

Answer: 4- The number of cell divisions a cell is capable of undergoing

The telomere is a DNA sequence at the end of each chromosome which becomes

progressively shorter with each division the cell undergoes.

When it is reduced to a critical length the cell is not capable of dividing. The enzyme telomerase is able to lengthen the telomere thus preventing this occurring.

[Q: 3538] OnExamination 2012 - Basic Science

Is it true that phosphorylation of protein tyrosine residues is associated with the following?

- 1- Alzheimer's disease
- 2- Cell signalling pathways
- 3- Creutzfeldt-Jakob disease
- 4- Protein degradation
- 5- Protein synthesis

Answer & Comments

Answer: 2- Cell signalling pathways

Phosphorylation of specific tyrosine residues of components of cell signalling pathways is often a key event in the activation of the pathway.

[Q: 3539] OnExamination 2012 - Basic Science

Northern blotting is a technique that can be used to detect which of the following?

- 1- Antibodies
- 2- DNA
- 3- Plasmids
- 4- Protein
- 5- RNA

Answer & Comments

Answer: 5- RNA

Northern blotting is a means of detecting ribonucleic acid (RNA), frequently used to quantify specific mRNA transcript levels.

[Q: 3540] OnExamination 2012 - Basic Science

Which of the following stimulate the generation of cyclic AMP as the second messenger?

- 1- Cholera toxin
- 2- Growth hormone (GH)
- 3- Nitric oxide
- 4- Pioglitazone
- 5- Tissue necrosis factor (TNF) alpha

Answer & Comments

Answer: 1- Cholera toxin

Nitric oxide generates cyclic guanosine monophosphate (cGMP) as the second messenger and pioglitazone acts through agonism of peroxisome proliferator activating receptor (PPAR) gamma.

Calcitonin cholera toxin binds to the ganglioside receptors and causes excessive production of cyclic adenosine monophosphate (cAMP) which leads to the activation of luminal sodium pumps and the secretory diarrhoea.

GH like TNF alpha acts on the GH/cytokine superfamily of receptors which function via the janus kinases/signal transducers and activators of transcription (JAK-STAT) pathway.

[Q: 3541] OnExamination 2012 - Basic Science

Apoptosis is the process of programmed cell death and occurs in cells that have damaged DNA.

A mediator of this process is a tumour suppressor gene that inhibits mitosis and promotes apoptosis.

This gene is which of the following?

- 1- BCL-2
- 2- Caspases
- 3- Fas (CD95)
- 4- p53
- 5- Ras

Answer & Comments

Answer: 4- p53

BCL-2 is an inhibitor of apoptosis.

Fas is a cell receptor and caspases are present in all cells; both promote apoptosis but are not tumour suppressor genes.

Ras is an oncogene.

[Q: 3542] OnExamination 2012 - Basic Science

A plasmid is best described as which of the following?

- 1- A recombinant section of DNA
- 2- A small viral particle
- 3- Bacterial DNA separate from the chromosome
- 4- Consisting of multiple copies of a single gene
- 5- Having multiple origins of replication

Answer & Comments

Answer: 3- Bacterial DNA separate from the chromosome

Plasmids are circular molecules of bacterial deoxyribonucleic acid (DNA) separate from the bacterial chromosome.

They usually:

Are small

Consist of a few thousand base pairs

Carry one or a few genes, and

Have a single origin of replication.

Genes on plasmids with multiple copies are usually expressed at higher levels.

In nature these genes often encode for proteins such as those needed for bacterial resistance.

Plasmids can be used to clone genes by splicing a particular gene into a plasmid and then allowing the bacteria to multiply - this is then called recombinant plasmid DNA.

[Q: 3543] OnExamination 2012 - Basic Science

The polymerase chain reaction (PCR) is used to amplify small amounts of deoxyribonucleic acid (DNA) for further analysis. First the DNA double helix must be split into two strands.

By which of the following is this achieved?

- 1- Alkali solution
- 2- Centrifugation
- 3- DNA polymerase
- 4- Heating to nearly 100°C
- 5- Viral reverse transcriptase

Answer & Comments

Answer: 4- Heating to nearly 100°C

To the small sample of DNA are added two oligonucleotides with sequences that have affinity for both ends of the area of DNA that is being studied.

A thermostable DNA polymerase is also added.

At 94°C DNA literally melts into two single strands and with cooling the oligonucleotides bind to the areas surrounding the particular area of DNA that is being analysed.

These act as primers for the DNA polymerase and a new double helix of DNA is formed.

The cycle is repeated doubling the amount of DNA each time.

[Q: 3544] OnExamination 2012 - Basic Science

A patient is found to have an acquired syndrome associated with defective breakdown and disposal of intracellular fatty acids.

Which intracellular organelle is concerned with the breakdown of fatty acids?

- 1- Golgi apparatus
- 2- Lysosomes
- 3- Mitochondria
- 4- Peroxisomes
- 5- Smooth endoplasmic reticulum

Answer & Comments

Answer: 4- Peroxisomes

Mitochondria are concerned with aerobic cell respiration and Golgi bodies are likely to be responsible for transporting products synthesised in the smooth endoplasmic reticulum.

Smooth endoplasmic reticulum is a site of lipid synthesis within the cell.

Lysosomes (lysis- breakage, soma- body) contain digestive enzymes which break down expendable cell organelles, engulfed viruses and other intracellular detritus.

Peroxisomes are responsible for the metabolism of fatty acids within cells.

[Q: 3545] OnExamination 2012 - Basic Science

A 59-year-old woman presents with a two week history of back pain.

On admission, WCC is $24 \times 10^9/L$ (4-11). MR scan reveals a thoracic spine discitis associated with an epidural abscess.

What is the likeliest cause?

- 1- Brucella melitensis
- 2- Escherichia coli
- 3- M. tuberculosis
- 4- Methicillin-resistant S. aureus (MRSA)
- 5- Methicillin-sensitive S. aureus (MSSA)

Answer & Comments

Answer: 5- Methicillin-sensitive S. aureus (MSSA)

In the United Kingdom, MSSA is a more common cause of severe community-acquired infections than MRSA.

Brucella and TB can cause osteomyelitis in patients from countries where these infections are endemic but do not cause a raised white cell count.

Escherichia coli is an unlikely cause of vertebral osteomyelitis.

[Q: 3546] OnExamination 2012 - Basic Science

An 80-year-old man is admitted to hospital with a CVA.

Due to incontinence secondary to immobility, a urinary catheter is inserted. Five days later the patient becomes severely septic.

What is the likeliest cause of his sepsis?

- 1- Aspiration pneumonia
- 2- Clostridium difficile diarrhoea
- 3- Infected intravascular catheter
- 4- Infected pressure sores
- 5- Urinary tract infection, catheter associated

Answer & Comments

Answer: 5- Urinary tract infection, catheter associated

Urinary catheters are a risk to patients and should only be inserted in patients to relieve obstruction or when monitoring of urine output is required for medical reasons.

[Q: 3547] OnExamination 2012 - Basic Science

A 69-year-old woman develops a fever 10 days after gastrointestinal surgery. She is receiving total parenteral nutrition (TPN).

Blood cultures grow Candida albicans.

What is the likeliest source of her candidaemia?

- 1- Gastrointestinal (GI) tract
- 2- Intravascular catheter
- 3- None of these
- 4- Sputum
- 5- Urine

Answer & Comments

Answer: 2- Intravascular catheter

Previous GI tract surgery, previous exposure to antibiotics and TPN administered through a central intravascular catheter are risk factors for candidaemia.

[Q: 3548] OnExamination 2012 - Basic Science

A 59-year-old female presents with dizziness, malaise and a fluctuating Glasgow coma score (GCS). CT scan of the head is normal.

CSF examination reveals the following:

WCC 4480 (99% neutrophils) < 1

RCC 700 < 1

Protein 2.02 g/L < 0.4

Glucose 1.4 mmol/L (plasma glucose 5.6 mmol/L)

Blood cultures reveal Gram positive cocci in pairs.

What is the likeliest cause of this patient's meningitis?

- 1- L. monocytogenes
- 2- N. meningitidis
- 3- S. agalactiae
- 4- S. aureus
- 5- Streptococcus pneumoniae

Answer & Comments

Answer: 5- Streptococcus pneumoniae

N. meningitidis is a clinical possibility but these would appear as Gram negative diplococci in blood cultures.

L. monocytogenes are Gram positive rods and a rare cause of meningitis in the elderly or immunocompromised.

S.agalactiae is the commonest cause of late onset neonatal disease and rarely causes meningitis in adults.

[Q: 3549] OnExamination 2012 - Basic Science

A 43-year-old female presents with fever, headache and confusion. CT scan reveals a space occupying lesion.

In theatre, pus is aspirated from the lesion and a Gram stain reveals a large number of polymorphs, and gram positive cocci in chains.

What is the likeliest cause of this brain abscess?

- 1- Enterococcus faecalis
- 2- Group A Streptococci
- 3- Group B Streptococci
- 4- S. milleri
- 5- Streptococcus pneumoniae

Answer & Comments

Answer: 4- S. milleri

The other organisms are not commonly recognised causes of brain abscesses.

Streptococcus milleri is a common cause of brain abscesses and is often associated with sinus infection. Streptococci are gram positive cocci which characteristically form chains (in contrast to staphylococci which clump/cluster).

[Q: 3550] OnExamination 2012 - Basic Science

A 15 week pregnant woman is exposed to a family member with chickenpox.

What is the most appropriate next step?

- 1- Advise serial ultrasound scans
- 2- Check varicella zoster IgG status
- 3- Counsel high risk of congenital varicella syndrome
- 4- Give varicella zoster immunoglobulin (VZIg)
- 5- Reassure

Answer & Comments

Answer: 2- Check varicella zoster IgG status

Despite exposure in the first trimester, the risk of congenital varicella syndrome remains low.

Unlike exposure to Erythrovirus B19, serial ultrasound scans are not recommended.

It is important to elucidate the varicella zoster serostatus of the mother as only if seronegative should varicella zoster IgG be administered. This is provided it is given within 10 days of exposure, the minimum incubation period of chickenpox.

[Q: 3551] OnExamination 2012 - Basic Science

A patient with TB is receiving the following drugs as induction phase during treatment;

rifampicin, isoniazid, pyrazinamide, ethambutol and pyridoxine.

Which drug is most likely to cause peripheral neuropathy?

- 1- Ethambutol
- 2- Isoniazid
- 3- Pyrazinamide
- 4- Pyridoxine
- 5- Rifampicin

Answer & Comments

Answer: 2- Isoniazid

Supplementation with pyridoxine, vitamin B6, reduces the risk.

[Q: 3552] OnExamination 2012 - Basic Science

What is the mechanism of resistance for rifampicin resistant Mycobacterium tuberculosis?

- 1- Alteration in cell wall permeability
- 2- Alteration of the DNA dependent RNA transcriptase
- 3- Alteration of penicillin binding proteins (PBPs)
- 4- Efflux mechanism
- 5- Production of the inactivating enzyme, penicillinase

Answer & Comments

Answer: 2- Alteration of the DNA dependent RNA transcriptase

Rifampicin is a bacteriostatic antibiotic which acts by inhibiting protein synthesis.

Mutations in rpoB gene cause alterations in the bacterial DNA dependent RNA transcriptase which prevents the binding of rifampicin.

[Q: 3553] OnExamination 2012 - Basic Science

What is the mechanism of resistance for penicillin resistant Streptococcus pneumoniae?

- 1- Alteration in cell wall permeability
- 2- Alteration of the DNA dependent RNA transcriptase
- 3- Alteration of penicillin binding proteins (PBPs)
- 4- Efflux
- 5- Production of the inactivating enzyme, penicillinase

Answer & Comments

Answer: 3- Alteration of penicillin binding proteins (PBPs)

Penicillin is a bactericidal antibiotic which acts by inhibiting cell wall synthesis.

Mutations in PBPs, enzymes required for cell wall synthesis, result in penicillin resistance.

[Q: 3554] OnExamination 2012 - Basic Science

A 45-year-old male intravenous drug user (IVDU) presents to hospital with fever and a productive cough.

On examination, a pansystolic murmur is heard at the left sternal edge. CXR reveals multiple cavitary lesions.

What is the likeliest explanation?

- 1- Aortic valve endocarditis with embolisation
- 2- Aspiration pneumonia
- 3- Mitral valve endocarditis with embolisation
- 4- Pulmonary TB
- 5- Tricuspid valve endocarditis with embolisation

Answer & Comments

Answer: 5- Tricuspid valve endocarditis with embolisation

IVDUs are susceptible to *S. aureus* tricuspid valve endocarditis due to auto-inoculation of *S. aureus* during injection.

In IVDUs, pulmonary TB and aspiration pneumonia are less likely causes of multiple pulmonary cavitary lesions.

[Q: 3555] OnExamination 2012 - Basic Science

A patient is diagnosed with an abnormality of oligopeptide disposal.

Which intracellular organelle is associated with the metabolism of oligopeptides?

- 1- Golgi apparatus
- 2- Lysosomes
- 3- Peroxisomes
- 4- Ribosomes
- 5- Smooth endoplasmic reticulum

Answer & Comments

Answer: 2- Lysosomes

Lysosomes (lysis- breakage, soma- body), carry hydrolases that degrade

Nucleotides

Proteins

Lipids

Phospholipids.

They also remove carbohydrate, sulfate, or phosphate groups from molecules.

Ribosomes are intimately associated with the rough endoplasmic reticulum and are responsible for protein translation.

Peroxisomes are responsible for the metabolism of fatty acids within cells.

[Q: 3556] OnExamination 2012 - Basic Science

A 45-year-old Ghanaian man presents to hospital with a right sided middle lobe pneumonia.

Streptococcus pneumoniae is isolated from blood cultures.

What is the likeliest underlying association?

- 1- Common variable immunodeficiency (CVID)
- 2- HIV
- 3- HTLV-1
- 4- IgA deficiency
- 5- Terminal complement deficiency

Answer & Comments

Answer: 2- HIV

Streptococcus pneumoniae, is a Gram-positive diplococcus which is carried asymptomatically in approximately 50% of people. It can cause both non-invasive and invasive disease. Invasive pneumococcal disease (IPD) refers to disease in which the bacterium enters a sterile site such as blood, cerebrospinal fluid, pleural fluid or pericardial fluid. Non-invasive disease includes otitis media, sinusitis, pneumonia and bronchitis. This gentleman has grown the organism from his blood cultures, and therefore has IPD by definition. This is a major cause of morbidity and mortality in children and adults.

Invasive pneumococcal disease (IPD) is 20-30 times more common in HIV infected patients compared to non-HIV infected patients. Consideration should be given to offering HIV testing to all patients with IPD presenting to hospital.

Other immunodeficiency syndromes are associated with an increased risk of IPD, but the majority of these present in childhood. These include X-linked (Bruton's) agammaglobulinaemia, common variable

immunodeficiency, asplenia (anatomical or functional) and sickle cell disease.

The other causes of immunodeficiency are not associated with IPD.

[Q: 3557] OnExamination 2012 - Basic Science

A 45-year-old Indian man is seen by his GP with oropharyngeal candidiasis and treated with fluconazole. One month later he developed a dry cough, night sweats and shortness of breath (SOB) on exertion.

On admission to hospital CXR revealed bilateral ground glass shadowing.

What is the likeliest diagnosis?

- 1- Late onset asthma
- 2- Pneumococcal pneumonia
- 3- Pneumocystis carinii pneumonia (PCP)
- 4- Tuberculosis (TB)
- 5- Viral pneumonitis (H1N1)

Answer & Comments

Answer: 3- Pneumocystis carinii pneumonia (PCP)

HIV diagnoses are often delayed in groups of patients other than sub-Saharan Africans and men who have sex with men.

Guidance in 2008 aimed to reduce barriers to HIV testing but there is still reluctance to offer HIV testing to patients, despite unusual clinical presentations, outside traditional risk groups.

[Q: 3558] OnExamination 2012 - Basic Science

An 85-year-old woman was admitted to hospital complaining of a swollen right leg.

On examination she had extensive right leg erythema with blisters. Subsequently she became confused and hypotensive and was transferred to ITU for ventilation and inotropic support.

What is the likeliest cause of her condition?

- 1- Group C Streptococcus
- 2- Group G Streptococcus
- 3- MRSA
- 4- S. aureus
- 5- S. pyogenes (Group A Streptococcus)

Answer & Comments

Answer: 5- S. pyogenes (Group A Streptococcus)

Groups C and G Streptococci are less virulent than Group A Streptococci and rarely cause severe disease.

Occasionally, S. aureus may cause severe disease but rarely an extensive community-acquired cellulitis.

[Q: 3559] OnExamination 2012 - Basic Science

A multiple drug resistant Escherichia coli was isolated from the urine of a patient with severe sepsis.

What is the likely mechanism of resistance?

- 1- Alteration of drug target
- 2- Drug efflux
- 3- Drug impermeability
- 4- Extended spectrum beta-lactamase (ESBL) production
- 5- Penicillinase production

Answer & Comments

Answer: 4- Extended spectrum beta-lactamase (ESBL) production

Some Escherichia coli isolates produce an ESBL that inactivate second and third generation cephalosporins.

The class of drugs that will most reliably treat these infections are the carbapenems.

[Q: 3560] OnExamination 2012 - Basic Science

A 15 week pregnant woman is exposed to a family member with an erythematous rash. She has previously been immunised with MMR twice.

What is the most appropriate next test?

- 1- CMV IgG
- 2- Erythrovirus B19 IgG
- 3- Measles IgG
- 4- Rubella IgG
- 5- Toxoplasma IgG

Answer & Comments

Answer: 2- Erythrovirus B19 IgG

As she has had two MMR immunisations the patient will be immune against measles and rubella.

If further serological testing demonstrates seroconversion to Erythrovirus B19, the mother should be followed up with serial ultrasound scans.

If hydrops fetalis is detected, intrauterine blood transfusions should be considered.

[Q: 3561] OnExamination 2012 - Basic Science

A 43-year-old Nigerian presents with an eight month history of weight loss, fever and night sweats.

On examination she had left axillary lymphadenopathy.

What is the likeliest cause of her illness?

- 1- Carcinoma of the breast
- 2- HIV infection
- 3- Lymphoma
- 4- SLE
- 5- Tuberculosis (TB)

Answer & Comments

Answer: 5- Tuberculosis (TB)

The patient could be HIV co-infected but HIV itself is not a cause of pyrexia of unknown origin (PUO).

The patient should be offered HIV testing.

Other diagnoses are possible but less likely than TB.

[Q: 3562] OnExamination 2012 - Basic Science

A patient with multiple drug resistant (MDR) TB is receiving prolonged treatment with moxifloxacin.

Which side effect is likely to occur as a result of prolonged administration?

- 1- Achilles tendinitis
- 2- Hepatotoxicity
- 3- Nephrotoxicity
- 4- Peripheral neuropathy
- 5- Retinopathy

Answer & Comments

Answer: 1- Achilles tendinitis

This is an idiosyncratic reaction associated with prolonged use of quinolones.

[Q: 3563] OnExamination 2012 - Basic Science

Gentamicin, 7 mg/kg once daily, is administered to an elderly patient with severe urosepsis.

Twenty-four hours post administration gentamicin levels are more than 2 mg/l.

Which of the following complications would you expect?

- 1- Hepatotoxicity
- 2- Nephrotoxicity

- 3- Ototoxicity
- 4- Peripheral neuropathy
- 5- Retinopathy

Answer & Comments

Answer: 2- Nephrotoxicity

Prolonged exposure to gentamicin is likely to cause nephrotoxicity, particularly in elderly patients with renal impairment.

Therefore the next dose of gentamicin should not be given if the gentamicin trough exceeds 2 mg/l.

[Q: 3564] OnExamination 2012 - Basic Science

What is the mechanism of action of ciprofloxacin?

- 1- Cell wall inhibition
- 2- Inhibition of protein synthesis (translation)
- 3- Inhibition of protein synthesis (transcription)
- 4- Inhibition of folic acid metabolism
- 5- Interference with DNA replication

Answer & Comments

Answer: 5- Interference with DNA replication

Ciprofloxacin interferes with DNA synthesis by disrupting the function of DNA gyrase.

[Q: 3565] OnExamination 2012 - Basic Science

What is the mechanism of action of trimethoprim?

- 1- Cell wall inhibition
- 2- Inhibition of protein synthesis (translation)
- 3- Inhibition of protein synthesis (transcription)
- 4- Inhibition of folic acid metabolism

- 5- Interference with DNA replication

Answer & Comments

Answer: 4- Inhibition of folic acid metabolism

Trimethoprim interferes with the action of dihydrofolic reductase (DHFR), which is an enzyme that converts dihydrofolic to tetrahydrofolic acid, an essential stage in bacterial purine and, ultimately DNA synthesis.

[Q: 3566] OnExamination 2012 - Basic Science

What is the mechanism of action of glycopeptides (for example, vancomycin)?

- 1- Cell wall inhibition
- 2- Inhibition of protein synthesis (translation)
- 3- Inhibition of protein synthesis (transcription)
- 4- Inhibition of folic acid metabolism
- 5- Interference with DNA replication

Answer & Comments

Answer: 1- Cell wall inhibition

Glycopeptides inhibit cell wall synthesis through steric hindrance of peptidoglycans, components of the bacterial cell wall.

[Q: 3567] OnExamination 2012 - Basic Science

What is the mechanism of action of gentamicin, when used synergistically with benzylpenicillin to treat an infective endocarditis caused by Streptococcus viridans?

- 1- Cell wall inhibition
- 2- Inhibition of protein synthesis (translation)
- 3- Inhibition of protein synthesis (transcription)
- 4- Inhibition of folic acid metabolism
- 5- Interference with DNA replication

Answer & Comments

Answer: 2- Inhibition of protein synthesis (translation)

Gentamicin is synergistic to the action of benzylpenicillin.

Benzylpenicillin is bactericidal, inhibiting cell wall synthesis, enabling gentamicin to enter the bacterial cell.

It acts at the level of the ribosome, inhibiting protein synthesis.

[Q: 3568] OnExamination 2012 - Basic Science

You would be likely to observe the lowest heritability score in:

- 1- Cleft lip/palate
- 2- Congenital heart disease
- 3- Cystic fibrosis
- 4- Mumps
- 5- Spina bifida

Answer & Comments

Answer: 4- Mumps

Mumps is due to an infective agent and hence has the lowest heritability score.

All the other disorders have a genetic aetiological component, for example, cystic fibrosis is autosomal recessive.

[Q: 3569] OnExamination 2012 - Basic Science

A 17-year-old male who appears tall and thin for his age, presents with a high arch palate, chest wall deformities and livedo reticularis.

Which of the following is also associated with this syndrome?

- 1- Autosomal dominance
- 2- Methionine accumulation
- 3- Osteopetrosis

4- Positive Guthrie test

5- Upward dislocation of the lens

Answer & Comments

Answer: 2- Methionine accumulation

This syndrome is most likely to be homocystinuria.

Marfan's syndrome is associated with upward dislocation of the lens, but not with livedo reticularis, which is seen in homocystinuria due to the venous thrombosis in the small vessels of the skin.

Homocystinuria is associated with downward dislocation of the lens, and is an autosomal recessive disorder.

Osteoporosis, and not osteopetrosis is seen in homocystinuria.

A positive Guthrie test is associated with phenylketonuria.

Reduced activity of cystathionine-synthase results in accumulation of homocysteine and methionine, interfering with collagen cross-linking, which is the cardinal feature of homocystinuria.

[Q: 3570] OnExamination 2012 - Basic Science

Which of the following conditions is most likely to be detectable by growth monitoring?

- 1- Hyperthyroidism
- 2- Hypothyroidism
- 3- Insulin dependent diabetes mellitus
- 4- Pseudohypoparathyroidism
- 5- XYY syndrome

Answer & Comments

Answer: 2- Hypothyroidism

Benefits of growth monitoring include:

Early detection of conditions such as:

Hypothyroidism

Growth hormone insufficiency

Syndromes: Turner, Russell-Silver, Noonan's, skeletal dysplasias

Growth impairment, for example, coeliac disease, inflammatory bowel disease or chronic renal failure

Intracranial tumours

Short normal children

Children with short stature

Health promotion: impaired growth may be associated with child abuse or neglect for example

Focus of interest for parents.

Public health aspects:

Secular trend of increasing growth

Linking growth patterns in fetal life and early infancy with adult patterns of disease

Link between height and social circumstances.

[Q: 3571] OnExamination 2012 - Basic Science

A 69-year-old patient is admitted for routine hernia surgery.

Pre-operatively, his serum sodium concentration is 122 mmol/l. The surgical team have asked for medical advice regarding the cause of his hyponatraemia. You have assessed him and believe he has diuretic-induced hyponatraemia and dehydration.

According to guidelines, which fluid should be used to resuscitate him?

- 1- 0.45% Saline
- 2- 0.9% Saline
- 3- 5% Dextrose
- 4- Gelofusine

5- Hartmann's solution

Answer & Comments

Answer: 5- Hartmann's solution

Fluid resuscitation is an important and often poorly understood skill. The recent multi-disciplinary GIFTASUP guidelines were endorsed by professional organisations representing surgeons, anaesthetists, biochemists and physicians, including nephrologists.

The guidelines state:

'Saline depletion, for example due to excessive diuretic exposure, is best managed with a balanced electrolyte solution such as Hartmann's.'

In other clinical situations:

Losses from diarrhoea/ileostomy/small bowel fistula/ileus/obstruction should be replaced volume for volume with Hartmann's or Ringer's lactate/acetate type solutions.

Excessive losses from gastric aspiration/vomiting should be treated pre-operatively with an appropriate crystalloid solution which includes an appropriate potassium supplement.

Hypochloraemia is an indication for the use of 0.9% saline, with appropriate additions of potassium and care not to produce sodium overload.

Reference:

Guidelines on Intravenous fluid therapy for adult surgical patients, multidisciplinary guideline 2011.

[Q: 3572] OnExamination 2012 - Basic Science

Which physiological mechanism controls water loss (aquaresis) without loss of sodium (natriuresis)?

- 1- Arginine vasopressin

- 2- Atrial natriuretic peptides
- 3- Renal glomerular filtration rate
- 4- Renin-angiotensin-aldosterone system (RAAS)
- 5- Thirst

Answer & Comments

Answer: 1- Arginine vasopressin

Disorders of sodium concentrations are closely linked with water homeostasis.

When sodium is excreted, water usually follows, such as occurs with diuretic therapy and natriuretic peptides. When sodium is retained, water will also be retained by the kidneys. This is seen in prolonged activation of the RAAS in heart failure where there is increased total body water and total body sodium. The only hormone system which can disrupt this is the arginine vasopressin (AVP) system, also known as anti-diuretic hormone.

AVP maintains a close control of water homeostasis by the use of a water channel called aquaporin. AVP, travelling in the blood stream stimulates:

Short term release of pre-formed aquaporin which is incorporated into the collecting duct basement cell membrane and

Transcription and translation to make more aquaporin, on a longer-term basis.

Aquaporin is a very specialised channel protein with a very tight lumen, which allows only water through.

Water from the lumen of the collecting duct enters the aquaporin allowing concentration of the urine and conservation of water which re-enters body cells. Sodium and other ions cannot get through the aquaporin channels.

Disorders of AVP include:

SIADH - syndrome of inappropriate antidiuretic hormone (ADH). ADH levels are

high causing conservation of water without conservation of sodium. This causes hyponatraemia with inappropriately high loss of sodium in the urine.

Diabetes insipidus - inadequate ADH leads to conservation of sodium and loss of water. Patients become hyperosmolar and hypernatraemic with polyuria and polydipsia.

[Q: 3573] OnExamination 2012 - Basic Science

Which gut hormone promotes the synthesis of intrinsic factor?

- 1- Cholecystokinin (CCK)
- 2- Gastric inhibitory peptide (GIP)
- 3- Gastrin
- 4- Secretin
- 5- Vasoactive intestinal peptide (VIP)

Answer & Comments

Answer: 3- Gastrin

Intrinsic factor

Intrinsic factor is a glucoprotein secreted from the parietal cells of the stomach in response to gastrin, food or histamine. Many substances can bind Vitamin B₁₂ in the gut, but only intrinsic factor can aid its transportation across the mucosal wall. When the Vitamin B₁₂ bound to intrinsic factor reaches the terminal ileum, it binds to receptors on the surface of the mucosal cells and is able to cross the membrane and enter the cytoplasm. The intrinsic factor is then replaced by transcobalamin II which transports the B₁₂ out of the cell and into the bloodstream.

Gastrin

- Big, little and mini forms of gastrin are made in the G-cells of the gastric antrum and duodenum called G-34, G-17 and G-14 respectively

- Made from cleavage of a precursor molecule, preprogastrin
- Multiple fragments exist; with variable degrees of biological activity. The smallest is a tetrapeptide (G-4) but it has reduced biological activity compared with larger molecules
- Once secreted, it enters the blood stream and travels to the gastric fundus where it stimulates the secretion of gastric acid

- Stimulus for secretion:

Antral distention

Amino acids partially digested in stomach - especially phenylalanine, glycine and tryptophan (gastric pH 5-7)

Caffeine, alcohol, hypoglycaemia, calcium

Vagal stimulation due to the smell and taste of food.

- Actions:

Production of gastric acid, pepsinogen and intrinsic factor

Promotes release of secretin

Promotes secretion of bile and pancreatic bicarbonate and enzymes

Increases intestinal and gastric motility

Promotes mucosal growth

Stimulates increased blood flow to stomach.

Production of which of the following cytokines is most likely to be involved in the pathogenesis of this patient's condition?

1- IL-2

2- IL-4

3- IL-18

4- Interferon alpha

5- Interferon gamma

Answer & Comments

Answer: 2- IL-4

This patient has an acute hypersensitivity reaction to a wasp sting.

Th2 CD4 positive lymphocytes are involved in the pathogenesis of anaphylaxis, via the production of IL-4/IL-13 that act on B cells to increase IgE production and precipitate the development of acute hypersensitivity.

IL-4 also exacerbates anaphylaxis by acting synergistically with other vasoactive mediators to increase vascular permeability.

Th1 cells lead to increased production of

Interferon gamma

IL-2

Tumour necrosis factor.

An increase in the Th1:Th2 ratio is associated with a reduction in the risk of allergic/hypersensitivity reactions.

[Q: 3574] OnExamination 2012 - Basic Science

A 22-year-old woman is admitted with symptoms of shortness of breath, facial and laryngeal oedema, erythema and hypotension consistent with anaphylaxis.

She had been stung by a wasp and remembers a very severe reaction in which her whole forearm swelled up the last time she was stung by a wasp some three years earlier.

[Q: 3575] OnExamination 2012 - Basic Science

You are designing a study of a novel autoimmune modulator which shows promise in the treatment of rheumatoid arthritis with extra-articular manifestations, such as pleural effusion.

As a possible test to define which population is suitable, you are considering human leucocyte antigen (HLA) subtyping.

Which HLA antigen type is associated with this type of presentation?

- 1- DQ-2
- 2- DR-1
- 3- DR-2
- 4- DR-3
- 5- DR-4

Answer & Comments

Answer: 5- DR-4

HLA DR-4 is associated with

Rheumatoid arthritis with extra-articular features

Drug induced systemic lupus erythematosus (SLE)

IgA nephropathy

Hypertrophic obstructive cardiomyopathy.

The HLA system determines how antigens are presented to T cells and thus determines response to viral infection and manifestations of autoimmune disease.

Emerging evidence suggests there may be differences in the response to T cell modulating therapies, depending on HLA subtype.

[Q: 3576] OnExamination 2012 - Basic Science

Which of the following is true of autosomal dominant breast cancer?

- 1- Autosomal dominant breast cancer affects females but not males
- 2- BRCA 2 mutations increase the risk of prostate cancer
- 3- Females with the BRCA1 mutation will develop breast cancer
- 4- It accounts for nearly half of all breast cancer cases in the United States

- 5- Penetrance is close to 100%, with nearly all gene carriers developing breast cancer by age 80

Answer & Comments

Answer: 2- BRCA 2 mutations increase the risk of prostate cancer

An estimated 5-10% of breast cancers are inherited.

Autosomal dominant inheritance is the main means of inheritance and the BRCA1 and BRCA2 mutations are two such genes.

BRCA1 is also associated with increased risk of pancreatic cancer, and BRCA2 is associated with pancreatic cancer, prostate cancer and melanoma.

It is important to remember that inheritance of these mutations leads to an increased risk of developing a malignancy, not the certainty of developing a malignancy.

[Q: 3577] OnExamination 2012 - Basic Science

Which of the following is typically elevated in Gaucher's disease?

- 1- Acid phosphatase
- 2- Alkaline phosphatase
- 3- Amylase
- 4- Glucocerebrosidase
- 5- Lipase

Answer & Comments

Answer: 1- Acid phosphatase

Gaucher's disease is the most frequent of the lysosomal storage diseases.

The condition is usually due to a catalytic deficiency of glucocerebrosidase. It is accompanied by many ill-understood plasma and metabolic abnormalities. These include a polyclonal immunoglobulin response that may

progress to monoclonal gammopathy, amyloidosis, or even frank myeloma.

Low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol fractions are abnormal in the plasma.

Some lysosomal enzymes are elevated including tartrate-resistant acid phosphatase, hexosaminidase, and a human chitinase, chitotriosidase. This latter enzyme has proved to be very useful for monitoring Gaucher's disease activity in response to treatment and may reflect the severity of the disease.

[Q: 3578] OnExamination 2012 - Basic Science

Alpha-glucosidase is defective in which of the following disorders?

- 1- Andersen disease (glycogen storage disorder type 4)
- 2- Cori's disease (glycogen storage disorder type 3)
- 3- McArdle's disease (glycogen storage disorder type 5)
- 4- Pompe's disease (glycogen storage disorder type 2)
- 5- Von Gierke's disease (glycogen storage disorder type 1)

Answer & Comments

Answer: 4- Pompe's disease (glycogen storage disorder type 2)

Some of the glycogen storage disorders can have muscle involvement. These include:

Pompe's disease or acid maltase deficiency

Cori's/Forbes' disease or amylo-1-6-glucosidase deficiency

McArdle's disease or myophosphorylase deficiency.

Andersen disease is a deficiency of amylo-1,4-1,6 transglucosidase.

Von Gierke's disease is a deficiency of glucose 6 phosphorylase.

[Q: 3579] OnExamination 2012 - Basic Science

A 78-year-old man who lives alone and prepares his own food is found to have numerous ecchymotic haemorrhagic areas around his hair follicles. The hairs are fragmented and several haematomas are present in the muscles of the arms and legs. Except for the absence of teeth, the rest of the physical examination is unremarkable.

Laboratory examination reveals a normal prothrombin time, APTT and full blood count is normal except for a haematocrit of 28%.

efficiency of which of the following is most likely to explain this patient's presentation?

- 1- Folate
- 2- Vitamin A
- 3- Vitamin C
- 4- Vitamin K
- 5- Zinc

Answer & Comments

Answer: 3- Vitamin C

This man has features of scurvy.

Scurvy is the clinical state arising from dietary deficiency of vitamin C (ascorbic acid). It results in impaired collagen synthesis. The typical pathological manifestations of vitamin C deficiency are noted in dentine, osteoid and capillary vessel wall tissues.

Clinical features include

Gum swelling

Friability

Bleeding, and infection with loose teeth

Mucosal petechiae

Scleral icterus (late, probably secondary to haemolysis)

and pale conjunctiva are seen.

Fractures

Dislocations

Tenderness of bones

are common in children.

Bleeding into muscles and joints may be seen.

Perifollicular hyperkeratotic papules

Perifollicular haemorrhages

Purpura, and

Ecchymoses

are the classical skin manifestations of scurvy.

[Q: 3580] OnExamination 2012 - Basic Science

Which of the following suggests a diagnosis of Hurler's syndrome rather than Hunter's syndrome?

- 1- Cardiomyopathy
- 2- Cloudy cornea
- 3- Mental retardation
- 4- Skeletal abnormalities
- 5- X linked inheritance

Answer & Comments

Answer: 2- Cloudy cornea

Hunter's syndrome (MPS-2) is of X linked inheritance. The corneas are clear. The skeletal involvement tends to be mild with no gibbous present, though scoliosis is often found.

Mental retardation and heart involvement are less severe than in Hurler's syndrome.

Hurler's syndrome (MPS-1) is autosomal recessive in inheritance and is associated with

cloudy cornea. There is severe mental retardation, and gibbous deformation of the spine is characteristic. There is the characteristic coarse facies with hepatosplenomegaly.

[Q: 3581] OnExamination 2012 - Basic Science

Which of the following is true regarding chromosomes?

- 1- A fetus with triploidy will have 47 chromosomes
- 2- Down's syndrome is most commonly due to an extra copy of chromosome 21 inherited from the father
- 3- Heterochromatin is mostly composed of active genes
- 4- Telomeres provide the point of attachment to the mitotic spindle
- 5- The normal human karyotype contains 22 pairs of autosomes

Answer & Comments

Answer: 5- The normal human karyotype contains 22 pairs of autosomes

The human karyotype consists of 22 pairs of autosomes and 1 pair of sex chromosomes.

Down's syndrome is most commonly due to trisomy of C21 with the majority a consequence of non-disjunction within the ovum.

Trisomy results in 47 chromosomes whereas triploidy is the presence of three complete sets of chromosomes instead of two in all cells.

Heterochromatin is of little genetic significance containing mostly inactivated genes.

Telomeres are the distal extremities of the chromosomal arms but the centromeres

provide the point of attachment to the mitotic spindle.

[Q: 3582] OnExamination 2012 - Basic Science

You are looking after a 48-year-old patient with alcohol-related liver disease and varices. She was admitted the previous day with haematemesis and is currently nil-by-mouth awaiting an endoscopy with variceal banding. She weighs 50 kg.

Her blood test results are as follows:

Test result reference range:

Na 122 mmol/l/135-145

K 4.2 mmol/l/3.5-5.2

Creatinine 82 µmol/l/80-120

You wish to assess her requirements for IV fluids, while she is nil-by-mouth.

What is her daily potassium requirement?

- 1- None
- 2- 10 mmol/l
- 3- 25 mmol/l
- 4- 50 mmol/l
- 5- 120 mmol/l.

Answer & Comments

Answer: 4- 50 mmol/l

Patients need around 1 mmol/kg per day to maintain body potassium reserves.

In general, patients who are nil-by-mouth awaiting procedures or surgery require maintenance doses of sodium and potassium. This is particularly important to prevent hypokalaemia as patients recovering from acute illness are often slow to normalise their potassium concentrations.

The multidisciplinary GIFTASUP guidelines regarding IV fluid therapy in adults state:

"In the adult, daily maintenance requirements are usually the reference nutrient intake (RNI) 70 mmol sodium, and 1500-2500 ml water. In the absence of kidney disease or hyperkalaemia potassium needs to be provided in amounts close to the RNI for adults (40-80 mmol/day) - bearing in mind that in the unfed, low insulin state potassium may equilibrate more slowly with the intracellular space than when insulin or nutritionally significant amounts of carbohydrate are being administered."

In the patient above, who has alcohol-related liver disease, there may be additional factors which may affect fluid and sodium prescription, such as oedema.

Reference:

Guidelines on Intravenous fluid therapy for adult surgical patients, multidisciplinary guideline 2011.

[Q: 3583] OnExamination 2012 - Basic Science

What serious complication can occur when hyponatraemia is corrected too rapidly?

- 1- Cerebral demyelination
- 2- Cerebellar dysarthria
- 3- Gait disturbance
- 4- Peripheral neuropathy
- 5- Postural hypotension

Answer & Comments

Answer: 1- Cerebral demyelination

Hyponatraemia, even in mild degrees, is associated with reduced survival and neurological sequelae.

Even at serum sodium concentrations of 130-135 mmol/l, patients may be at increased risk of falls, and at increased risk of fracturing. However, it is not clear if the adverse prognosis of hyponatraemia is due to low serum sodium as such, or if this just

represents a patient group with more comorbidities or polypharmacy.

Hyponatraemia causes

Fatigue

Muscle weakness

Gait disturbance

Falls

Disorientation

Cerebral oedema

Seizures

and death if untreated.

If hyponatraemia develops gradually (>48 hours) the body can use compensatory mechanisms. The risk of cerebral oedema is greater in patients with acute onset (<48 hours) who are unable to use these compensatory mechanisms.

The treatment of hyponatraemia however can also cause problems if it occurs too rapidly. The consequences include cerebral demyelination at pontine and extra-pontine sites. Many authorities recommend that increases in serum sodium of <12 mmol/24 hours are likely to be safe for the majority of patients.

Certain patients with hypokalaemia, liver disease, poor nutritional state or burns are at higher risk of demyelination and should have a rate of sodium correction of <8 mmol/24 hours.

[Q: 3584] OnExamination 2012 - Basic Science

Which of the following situations can cause a reduction in total body magnesium content?

- 1- Acute pancreatitis
- 2- Long term treatment with omeprazole
- 3- Myocardial infarction

4- Recovery from diabetic ketoacidosis

5- Refeeding syndrome

Answer & Comments

Answer: 2- Long term treatment with omeprazole

All of the conditions listed can be associated with hypomagnesaemia but many are due to a shift of magnesium from the blood into body cells, which are not necessarily associated with a change in total body magnesium levels. Hypomagnesaemia due to a shift between blood and cellular compartments may still require treatment and can cause symptoms if severe.

Omeprazole causes hypomagnesaemia which, if severe, can cause hypoparathyroidism and hypocalcaemia. The reasons for this are unclear, but it may be due to reduced uptake of Mg^{2+} ions in the gut. Omeprazole reduces acid production and raises stomach pH. An acid environment can aid release of metal ions from their binding sites in food molecules which facilitate absorption.

Causes of hypomagnesaemia include:

- Inadequate intake
- Malnutrition
- Alcohol dependence
- Malabsorption
- Inflammatory bowel disease
- Long term PPI therapy
- Gluten enteropathy
- Intestinal bypass
- Radiation enteritis
- Renal tubular disease
- Hyperaldosteronism
- Hyperparathyroidism

Obstructive uropathy

Potassium depletion

Drugs including diuretics, amphotericin, cisplatin, ciclosporin, amikacin, gentamicin, laxatives and tacrolimus

Intracellular shift

Post myocardial infarction

Post parathyroidectomy

Recovery from diabetic ketoacidosis (K⁺ and PO₄⁻ also enter cells)

Refeeding syndrome (PO₄⁻ also enters cells)

Acute pancreatitis.

Investigating the cause of hypomagnesaemia:

Blood magnesium levels can guide but do not accurately reflect total body magnesium status. Attempts to find a marker of cellular magnesium status include measuring erythrocyte or monocyte Mg but these are not generally available.

Urine Mg excretion is a useful guide. When there is inadequate intake or malabsorption, the kidneys would normally conserve Mg, giving urine Mg concentrations <7mmol/24 hours. The reference range is around 2-7 mmol/24 hours.

[Q: 3585] OnExamination 2012 - Basic Science

Which gut hormone is made in the I cells of the duodenum and jejunum?

- 1- Cholecystokinin (CCK)
- 2- Gastric inhibitory peptide (GIP)
- 3- Gastrin
- 4- Secretin
- 5- Vasoactive intestinal peptide (VIP)

Answer & Comments

Answer: 1- Cholecystokinin (CCK)

CCK is made in the I cells of the duodenum and jejunum. The structure, stimulus for secretion and actions of CCK are summarised below.

Gastrin - G cells of the gastric antrum and duodenum.

Secretin - S cells of the granular mucosa of the duodenum.

VIP is predominantly found in the nervous system and gut and is considered a neurotransmitter.

Cholecystokinin (CCK)

Made in I cells of duodenum, jejunum and enteric nerves

Structurally similar to gastrin

Actions:

Promotes gallbladder contraction and intestinal motility

Increases secretion of pancreatic enzymes including insulin, glucagons, pancreatic polypeptides

Role in satiety

Short half life, less than three minutes, cleared by the kidneys

Stimulus for secretion:

Mixtures of polypeptides and amino acids especially phenylalanine and tryptophan stimulate release but undigested protein does not

Gastric acid entering duodenum

Fatty acids, especially in micelles

Secretion inhibited by somatostatin.

Reference:

Tietz Textbook of Clinical Chemistry, 5th edition.

[Q: 3586] OnExamination 2012 - Basic Science

What is the most characteristic symptom of hypocalcaemia?

- 1- Abdominal pain due to peptic ulceration
- 2- Polyuria and polydipsia
- 3- Renal calculi
- 4- Tetany
- 5- Weakness due to hypokalaemia

Answer & Comments

Answer: 4- Tetany

Hypocalcaemia characteristically causes

Increased neuromuscular excitability, manifesting as tetany

Carpopedal spasm (Trousseau's sign)

Seizures

Hyperreflexia

Paraesthesia and

Hypotension.

Weakness can also occur but is not generally associated with hypokalaemia.

Chronic hypocalcaemia, even when mild, predisposes to cataract formation.

The other symptoms above are more typically associated with hypercalcaemia:

Peptic ulceration. Calcium stimulates gastrin release and promotes increased secretion of gastric acid.

Polyuria and polydipsia are typical, due to a type of nephrogenic diabetes insipidus - modification of the renal response to antidiuretic hormone causing dehydration.

Renal calculi occur with chronic hypercalcaemia.

Hypokalaemia can be due to hypercalcaemia as calcium inhibits reabsorption of potassium, promoting its loss in the urine.

[Q: 3587] OnExamination 2012 - Basic Science

Parents of a 6-year-old boy present concerned that their son may be carrying the gene for Huntington's disease.

The father was diagnosed with the disease at age 32. The mother has been genetically screened and is not a carrier of the gene.

What is the likelihood of their son suffering with Huntington's disease?

- 1- 0 risk
- 2- 1 in 2
- 3- 1 in 4
- 4- 1 in 8
- 5- 3 in 4

Answer & Comments

Answer: 2- 1 in 2

Huntington's disease (HD), a progressive, degenerative neurological disease, has an autosomal dominant mode of transmission.

This means that only one copy of the faulty gene is required in the genotype for the patient to be a sufferer.

With the above case, the father is heterozygous which means he himself only has one copy of the gene (two copies of the gene are very unlikely with extremely severe phenotypes probably incompatible with life) and the mother seems to have no copies of the gene.

In this case with an autosomal dominant disease, the likelihood of a child developing the disease is 1 in 2 as it is expected that 50% of the offspring of this couple will have a faulty gene.

Symptoms of this disease tend to start to develop in early middle age and include an unsteady gait and jerky involuntary movements, accompanied later by behavioural changes and progressive dementia.

The defective gene is located on chromosome 4.

Genetic screening is now available.

[Q: 3588] OnExamination 2012 - Basic Science

It has been suggested that cystic fibrosis (CF) (autosomal recessive) has a high prevalence in some populations because heterozygotes are resistant to the effects of chloride-secreting diarrhoea. *This is best described as an example of:*

- 1- Gene flow
- 2- Genetic drift
- 3- Linkage disequilibrium
- 4- Mutation
- 5- Natural selection

Answer & Comments

Answer: 5- Natural selection

Natural selection is the likely explanation as it appears that heterozygous for CF may offer some protection against diarrhoeal illnesses particularly cholera. Natural selection is defined as the process whereby organisms possessing certain characteristics that make them better adjusted to the environment tend to survive and reproduce in greater numbers, and are therefore able to transmit their qualities to succeeding generations.

Gene flow (also known as genetic migration) is the transfer of alleles or genes from one population to another. In humans it usually happens following migration (e.g. West African population with European in USA).

Genetic drift refers to the statistical drift over time of gene frequencies in a population, due to random sampling effects in subsequent generations.

Linkage disequilibrium is the occurrence of some combinations of alleles more or less often than would be expected from a random formation of haplotypes.

Mutation is a change in genetic sequence.

[Q: 3589] OnExamination 2012 - Basic Science

What test is used to confirm the diagnosis of Gaucher disease?

- 1- Abdominal ultrasound
- 2- Alkaline phosphatase
- 3- Bone marrow biopsy with Gaucher's cells identified
- 4- Clinical examination
- 5- Enzyme studies of blood leucocytes

Answer & Comments

Answer: 5- Enzyme studies of blood leucocytes

Gaucher disease is a genetic disorder characterised by complete or incomplete deficiency of the enzyme glucocerebrosidase, required for the metabolism of sphingolipid. Sphingolipids are normally found throughout the body but are particularly important in the grey matter of the brain and in myelin sheaths.

Gaucher's disease results in accumulation of glycosphingolipids in liver, spleen and bone marrow. The defective gene is located on chromosome 21 and around 200 mutations have been described. There is therefore a high degree of phenotypic variation.

Certain mutations result in complete deficiency of the enzyme, and present in infancy with severe clinical effects (typically types 2 and 3). Partial deficiency of the

enzyme results in a later presentation and more moderate clinical effects. Type 1 patients typically have 10-15% of enzyme activity and present in adulthood.

Type 1 disease: often presents in adulthood with organomegaly, haematological abnormalities such as anaemia, bleeding risk, abdominal pain and skeletal abnormalities.

Type 2 disease: frequently progressively fatal in infancy. Prominent neurological features are present including ophthalmoplegia, spasticity and CNS degeneration.

Type 3 disease: milder course with CNS involvement.

Diagnosis is through enzyme studies on whole blood leucocytes. Clinical examination and abdominal ultrasound may suggest the diagnosis but cannot provide biochemical confirmation. Bone marrow biopsy is not required in all patients but shows characteristic glycosphingolipid-containing macrophages called Gaucher's cells.

Acid phosphatase, chitotriosidase, macrophage inflammatory protein (MIP)-1?, MIP-1? and soluble CD163 can be used for surveillance of the disease.

Further reading (available through pubmed):

Harmanci O, Bayraktar Y. Gaucher disease: new developments in treatment and etiology. World J Gastroenterol 2008; 14(25): 3968-3973.

[Q: 3590] OnExamination 2012 - Basic Science

Which one of the following statements regarding X-linked recessive diseases is correct?

- 1- Are not usually associated with immune deficiency
- 2- Are usually associated with male infertility
- 3- Can occur with equal severity in males and females

4- Do not show anticipation

5- Include G6PD deficiency, ornithine transcarbamylase deficiency, hypophosphataemic rickets and von Willebrand's disease

Answer & Comments

Answer: 3- Can occur with equal severity in males and females

X linked recessive diseases can occur with the same severity in females in certain situations having

An affected father and carrier mother (seen in G6PD deficiency)

Turner's syndrome

X chromosome isodisomy

Unequal lyonisation,

also in

An XY individual with testicular feminisation syndrome

and where there is

An X/autosome translocation through a gene (DMD).

Fragile X syndrome shows anticipation with triplet repeat expansion.

Y linked diseases can be associated with male infertility.

There are several X linked immune deficiency syndromes and severe combined immune deficiency, chronic granulomatous disease, agammaglobulinaemia (Bruton's disease), and Wiscott-Aldrich syndrome.

Hypophosphataemic rickets is X linked dominant, and von Willebrand's disease is inherited in an autosomal dominant manner.

[Q: 3591] OnExamination 2012 - Basic Science

Which of the following is a characteristic feature of acute intermittent porphyria?

- 1- Autosomal recessive inheritance
- 2- Excessive faecal protoporphyrin excretion
- 3- Excessive urinary porphobilinogen during an acute attack
- 4- Hyponatraemia during attacks
- 5- Photosensitivity

Answer & Comments

Answer: 3- Excessive urinary porphobilinogen during an acute attack

Acute intermittent porphyria (AIP) causes the classic acute attacks of porphyria, with abdominal pain and neuropsychiatric symptoms. It is caused by reduced hepatic porphobilinogen deaminase activity, which is inherited in an autosomal dominant fashion. This leads to increased urinary porphobilinogen and aminolaevulinic acid, especially during attacks. The urine classically turns deep red on standing. Hyponatraemia is often present during acute attacks and may, in part, be due to inappropriate secretion of antidiuretic hormone.

Episodes of porphyria are more common in females, possibly due to the effects of oestrogens, and the onset is usually in adolescence. Attacks are characterised by motor polyneuropathy, hypertension, tachycardia, and abdominal pain associated with vomiting and constipation. Tubulointerstitial nephritis may be present. There is no photosensitivity or rash.

Attacks may be precipitated by drugs (including alcohol, benzodiazepines, rifampicin, oral contraceptives, phenytoin and sulphonamides), stress, pregnancy, premenstruation, infection and fasting.

Treatment is usually supportive, with high carbohydrate supplementation and withdrawal of precipitating factors. Daily haem arginate infusions can be given for 3-4 days.

Faecal protoporphyrin is raised in protoporphyria and variegate protoporphyria, but normal in AIP.

[Q: 3592] OnExamination 2012 - Basic Science

Which of the following would be most in keeping with a diagnosis of polymyalgia rheumatica (PMR)?

- 1- Erythema nodosum
- 2- Increased alkaline phosphatase
- 3- Raised creatine kinase (CK)
- 4- Shoulder and pelvic girdle pain in a 40-year-old man
- 5- Sudden loss of vision in one eye

Answer & Comments

Answer: 2- Increased alkaline phosphatase

Liver enzymes are elevated in most patients.

Visual disturbances are suggestive of temporal arteritis not PMR, and are due to ischaemic changes in ciliary arteries (optic neuritis/infarction) and less commonly due to central artery occlusion.

Raised CK occurs in polymyositis.

PMR is rare before the age of 50 years.

[Q: 3593] OnExamination 2012 - Basic Science

Which factor inhibits the release of growth hormone (GH) from the pituitary?

- 1- Fasting
- 2- Ghrelin
- 3- Hypoglycaemia

4- Somatostatin

5- Stress

Answer & Comments

Answer: 4- Somatostatin

Roles of somatostatin:

Inhibits GH release

Inhibits secretion of insulin and glucagons.

GH release is increased by:

Deep sleep

Fasting

Alpha adrenergic activity

Stress

Exercise

Sex steroids

Hypoglycaemia

Amino acids

Thyroxine

Ghrelin.

GH release is inhibited by:

Somatostatin

Cortisol

Beta adrenergic activity

Hyperglycaemia

Obesity

Free fatty acids

Hypothyroidism

IGF-1.

[Q: 3594] OnExamination 2012 - Basic Science

Hypermagnesaemia can occur during which of the following clinical situations?

1- Chronic administration of omeprazole

2- Chronic kidney disease

3- Refeeding syndrome

4- Untreated pre-eclampsia

5- Untreated renal calculi

Answer & Comments

Answer: 2- Chronic kidney disease

Hypermagnesaemia is much less common than hypomagnesaemia and is often iatrogenic in cause.

Causes of hypermagnesaemia:

Iatrogenic

Treatment with magnesium sulphate to prevent/treat seizures in patients with eclampsia or pre-eclampsia

Treatment with Mg containing antacids

Use of citrate-glucuronic acid solutions to dissolve renal calculi either through bladder irrigation or via a nephrostomy tube

Over-zealous IV treatment of hypomagnesaemia

Chronic use of Mg-containing enemas.

Other causes

Acute or chronic renal failure - release of Mg from tissues, Mg in dialysate, Mg in phosphate binding drugs

Familial hypocalciuric hypercalcaemia.

Interpretation of serum Mg results:

0.7-1.5 mmol/l: reference range

1.5-2.5 mmol/l: mild hypermagnesaemia - symptoms uncommon

2.5-5.0 mmol/l: moderate hypermagnesaemia - symptoms develop including hypotension, prolonged PR and QRS intervals on ECG, areflexia

>5.0 mmol/l: severe hypermagnesaemia - at risk of respiratory paralysis through inhibition of acetylcholine release and cardiac arrest.

Treatment:

Hypermagnesaemia does not always require treatment - if mild/moderate and iatrogenic, often it is enough to identify and stop the cause. In an emergency, dialysis or administration of IV calcium glucuronate (10 ml of 10%) will reduce the effects of hypermagnesaemia.

[Q: 3595] OnExamination 2012 - Basic Science

What is the mechanism of action of cyanide?

- 1- Inhibition of enzyme acetylcholinesterase
- 2- Inhibition of enzyme cytochrome oxidase c
- 3- Inhibition of enzyme pyruvate dehydrogenase
- 4- Prevention of mitochondrial replication
- 5- Promoting mutations in DNA

Answer & Comments

Answer: 2- Inhibition of enzyme cytochrome oxidase c

Cyanide causes the inhibition of the enzyme cytochrome oxidase c which is an essential part of the mitochondrial electron transfer chain (ETC). It therefore interferes with the basic process of cellular respiration, preventing the formation of ATP and causing rapid cell death.

Sarin gas and related agents cause inhibition of the enzyme acetylcholinesterase, causing levels of acetylcholine to build up in the nervous system causing prolonged sustained contraction of the diaphragm. This hinders and eventually paralyses normal breathing.

Arsenic causes inhibition of the enzyme pyruvate dehydrogenase which is necessary for the conversion of pyruvate to acetyl CoA.

This also interferes with the basic process of cellular respiration, as pyruvate formed during glycolysis cannot be changed to acetyl CoA to enter the Krebs's cycle.

Unfortunately, many agents also cause mutational damage to DNA, so if victims are fortunate enough to survive the initial insult, they may still have significant long term health repercussions. Arsenic and mustards are known for this, and carry risks of skin and haematological malignancy in the longer term. Arsenic can also accelerate atherosclerosis.

[Q: 3596] OnExamination 2012 - Basic Science

Chronic alcohol abuse is typically associated with which abnormal laboratory results?

- 1- Hypermagnesaemia
- 2- Increased carbohydrate deficient transferrin
- 3- Microcytosis
- 4- Reduced AST:ALT ratio
- 5- Reduced iron and ferritin concentrations

Answer & Comments

Answer: 2- Increased carbohydrate deficient transferrin

Unfortunately, most of the tests available are not specific to alcohol excess. However, a combination of several consistent abnormalities occurring together gives a better indication of the cause being alcohol-related.

Carbohydrate deficient transferrin (CDT) is usually elevated and gradually falls after weeks and months of abstinence. It is very useful in some situations, where verifying abstinence is of particular importance. However, it is an expensive, time-consuming and specialised test which limits its usefulness in routine clinical practice.

The following abnormalities are common in chronic alcohol dependence:

Macrocytosis

Elevated GGT - this is due to enzyme induction but does not necessarily indicate that there is liver damage

Hypertriglyceridaemia - can contribute to pancreatitis

Hyperuricaemia - can cause gout

Hypoglycaemia - can contribute to seizures and coma

Hypomagnesaemia

Hypogonadism

Thiamine deficiency

Increased carbohydrate deficient transferrin - considered a marker of chronic abuse and sometimes checked to ensure abstinence, for example, while awaiting liver transplantation

Iron levels are variable in alcohol dependence: hepatitis causes increased serum iron while poor diet can result in iron deficiency

Ferritin can be elevated in the acute phase response, but reduced in advanced liver disease due to possible reduced synthesis rates

Hyponatraemia and hypokalaemia are often seen in established liver disease

ALT is elevated in liver disease and hepatocellular damage

AST is elevated (but can also be increased in cardiac or muscular damage).

AST:ALT ratio can be elevated due to the mitochondrial effects of alcohol causing a disproportionate increase in AST. However, this is not specific.

[Q: 3597] OnExamination 2012 - Basic Science

A previously well 35-year-old patient presents with anxiety and weight loss. Serum corrected calcium is 2.95 mmol/l.

What is the most likely cause of his hypercalcaemia?

- 1- Addison's disease
- 2- Secondary hyperparathyroidism
- 3- Thyrotoxicosis
- 4- Vitamin D toxicity
- 5- Williams' syndrome

Answer & Comments

Answer: 3- Thyrotoxicosis

Hypercalcaemia is common and can be caused by:

Primary hyperparathyroidism - overproduction of parathyroid hormone (PTH) due to hyperplasia or an adenoma of the PTH glands.

Tertiary hyperparathyroidism - in a patient with chronic renal failure with prolonged hypocalcaemia the parathyroids become autonomous, even if renal function is improved with transplantation. This can lead to hypercalcaemia.

Malignancy - commonly myeloma, prostate, breast, lung, thyroid and kidney cancers.

Drugs: lithium, vitamin D overdose, vitamin A toxicity, thiazides, milk-alkali syndrome, familial hypercalcaemic hypocalciuria.

Thyrotoxicosis - most patients with thyrotoxicosis have minor alterations in serum calcium, but a minority have significant symptomatic hypercalcaemia, probably due to increased bone turnover. Treating the thyroid disease causes resolution of the hypercalcaemia.

Addison's disease - although it would be uncommon to have significant hypercalcaemia.

Granulomatous disease - sarcoidosis, leprosy, TB.

Infections: HIV, histoplasmosis.

Williams' syndrome - a rare genetic disease affecting chromosome 7 and characterised by hypercalcaemia in infancy, anxiety and learning disability.

Note that secondary hyperparathyroidism is a response to hypocalcaemia, not a cause of hypercalcaemia.

[Q: 3598] OnExamination 2012 - Basic Science

Which apolipoprotein is characteristically found in low density lipoproteins (LDL)?

- 1- Apo A-I
- 2- Apo B-100
- 3- Apo B-48
- 4- Apo C III
- 5- Apo E

Answer & Comments

Answer: 2- Apo B-100

The main apolipoprotein in LDL is ApoB-100, which contains several very hydrophobic areas responsible for binding large quantities of lipid. It also contains a domain allowing binding to the LDL receptor.

Apo A-I is the major apolipoprotein in high density lipoprotein (HDL), comprising around 70% of its protein. The remainder is largely Apo A-II. Apo A-I is thought to be responsible for reverse cholesterol transport.

Apo B-48 is the major apolipoprotein in chylomicrons and is a fragment of ApoB-100 and comes from the same gene. Apo B-48 is

only produced by the intestine and cannot bind to the LDL receptor.

Apo C-III is present in large amounts in very low-density lipoprotein (VLDL) and in lesser quantities in chylomicrons and HDL. It works to inhibit the enzyme lipoprotein lipase (LPL) and to reduce hepatic uptake of chylomicron and VLDL fragments.

Apo E is found in all lipoproteins except LDL. It is made in the liver and is subject to genetic polymorphisms which can affect chylomicron handling and accumulation in the population. It is important in the removal of chylomicron and VLDL remnants from the blood.

Reference:

Clinical Biochemistry: Metabolic and clinical aspects, Marshall & Bangert, 2nd edition, 2008.

[Q: 3599] OnExamination 2012 - Basic Science

What is the treatment for life-threatening hypokalaemia?

- 1- 10 ml 10% calcium gluconate with IV 0.9% NaCl with 40 mmol/l KCl infused over four hours
- 2- 10 ml 10% calcium gluconate with oral Sando-K tablets
- 3- 1L IV 0.9% NaCl with 40 mmol/l KCl infused over four hours
- 4- Dialysis
- 5- Insulin and 50% dextrose infusion

Answer & Comments

Answer: 3- 1L IV 0.9% NaCl with 40 mmol/l KCl infused over four hours

Hypokalaemia should be treated by administering potassium, either orally (if $K > 2.5$ with no symptoms or ECG changes) or intravenously (if $K < 2.5$ with symptoms or ECG changes).

IV treatment is required in life-threatening cases. Potassium should be given in NaCl.

Concentration should not exceed 40 mmol/l and no more than 10-20 mmol/hour should be given. Careful monitoring of potassium, sodium and creatinine concentrations with water balance is required.

Life-threatening hypokalaemia should ideally be managed with cardiac monitoring.

Check magnesium: hypomagnesaemia can cause refractory hypokalaemia.

The following are treatments for hyperkalaemia:

10 ml 10% calcium gluconate (or calcium chloride)

Insulin and dextrose infusion

Dialysis.

[Q: 3600] OnExamination 2012 - Basic Science

What is the main role of the gut hormone secretin?

- 1- Promotes gastric acid formation
- 2- Promotes secretion of bicarbonate by the pancreas
- 3- Reduces bile flow
- 4- Stimulates lipolysis and glycolysis
- 5- Vasodilatation and relaxation of smooth muscle in gut

Answer & Comments

Answer: 2- Promotes secretion of bicarbonate by the pancreas

Secretin promotes bicarbonate secretion, reduces gastric acid formation and increases bile flow.

Another gut hormone, VIP, stimulates lipolysis, glycolysis and relaxation of the smooth muscle of the gut.

The structure, stimulus for secretion and actions of these hormones are outlined below.

Secretin

Secreted by the S cells of the granular mucosa which are predominantly located in the duodenum.

Unlike gastrin, which is highly fragmented, there are no active fragmentary molecules of secretin - the whole molecule is required for biological activity.

Stimulation for secretion:

Acid in the duodenum (pH<4.5)

Secretion is inhibited by somatostatin

Very low concentrations of secretin are found in the blood - too low to measure accurately. The action of secretin is potentiated by CCK. The half life of secretin is 4 min.

Actions:

Stimulates bicarbonate secretion from pancreas

Stimulates bicarbonate and water secretion by the liver

Increases bile flow and gallbladder contractility

Reduces gastric and duodenal motility

Inhibits normal gastrin secretion and thus reduces gastric acid formation.

Vasoactive intestinal polypeptide (VIP)

Polypeptide hormone with structural similarities to GIP, secretin and glucagon.

VIP is predominantly found in the nervous system and gut and is considered a neurotransmitter.

It has a plasma half life of 1 min and is largely inactivated after a single pass through the liver.

Stimulation for secretion

Vagal stimulation

Relationship to gut stimuli and eating is unclear.

Actions

Vasodilatation and relaxation of smooth muscle in circulatory and GI systems

Promotes water and electrolytes secretion from the gut

Promotes secretion of pancreatic hormones

Stimulates lipolysis, glycolysis and inhibits gastric acid secretion.

Reference:

Tietz Textbook of Clinical Chemistry, 5th edition.

[Q: 3601] OnExamination 2012 - Basic Science

Which tumour marker has the highest specificity when used appropriately?

- 1- AFP
- 2- Bence Jones protein
- 3- CA 125
- 4- CA 19-9
- 5- LDH

Answer & Comments

Answer: 2- Bence Jones protein

Tumour markers ideally need to be both sensitive and specific.

Sensitivity - the ability of a test positively to identify people who have the disease, that is, not missing cases and avoiding false negatives.

Specificity - the ability of a test to give a normal result to people who do not have the disease, that is, appropriately reassuring unaffected patients and avoiding false positives.

In practice, no tumour marker is perfect and false positives and negatives can always occur. However, some perform better than others.

Bence Jones protein is specific for myeloma, false positives are rare, and therefore it is more specific than the other markers.

AFP is elevated in hepatocellular carcinoma and in teratomas but false positive results occur with non-malignant liver disease.

CA125 is used to identify patients with ovarian cancer but false positives occur due to ascites, other abdominal malignancies, endometriosis and pelvic inflammatory diseases.

CA 19-9 is elevated in patients with pancreatic and colorectal carcinomas but is also elevated in obstructive jaundice, cholangitis and cholestasis.

Lactate dehydrogenase (LDH) is a very non-specific marker but can be elevated in some haematological malignancies.

[Q: 3602] OnExamination 2012 - Basic Science

The CAPRIE study looked at whether aspirin or clopidogrel was most appropriate in patients at increased risk of cardiovascular disease to prevent the MACE composite endpoint, which consists of stroke, MI or cardiovascular death, re-hospitalisation or bleeding.

A substudy looked at 3,866 patients with a history of diabetes and found an event rate of 17.7% for patients taking aspirin, versus 15.6% for patients taking clopidogrel.

What is the number needed to treat (NNT) to prevent one event for patients taking clopidogrel versus aspirin?

- 1- 2.1
- 2- 15.6/17.7
- 3- 100/2.1
- 4- 100/15.6
- 5- 100/17.7

Answer & Comments

Answer: 3- 100/2.1

The number needed to treat to prevent one specified outcome event is 100 divided by the absolute risk reduction, in this case $17.7 - 15.6\% = 2.1\%$. This equals 48, meaning that 48 patients need to be treated with clopidogrel versus aspirin to prevent one stroke, MI cardiovascular death, bleed or hospitalisation.

For many studies now, papers quote the number needed to harm. This uses the same principle to establish the difference in absolute risk of an adverse event occurring between two treatment strategies, calculating a number needed to harm by dividing 100 by the absolute risk.

Calculation of both number needed to treat and number needed to harm for a new therapy allows clinicians to establish net clinical benefit.

[Q: 3603] OnExamination 2012 - Basic Science

A 24-year-old man presents to the clinic with his wife. They are keen to start a family, but are concerned because his brother suffers from hereditary haemorrhagic telangiectasia (HHT) and has suffered a number of upper GI haemorrhages over the past few years. Indeed, his father died of a large GI haemorrhage.

He has suffered no bleeding episodes over the past few years and has no skin vascular abnormalities. On examination his blood pressure is normal at 125/72 mmHg, and there are no skin abnormalities. Physical examination is entirely normal.

What is the approximate percentage chance of a male child of this couple inheriting HHT?

- 1- 0%
- 2- 25%
- 3- 50%
- 4- 66%
- 5- 100%

Answer & Comments

Answer: 1- 0%

HHT carries an autosomal dominant inheritance pattern.

Around 90% of patients with the disease are diagnosed by age 16, often because of a problem with nose bleeds. As such this man is extremely unlikely to have the condition, and as his wife is unaffected, the chances of a child, male or female suffering from the disorder is 0%.

[Q: 3604] OnExamination 2012 - Basic Science

A 26-year-old man presented with exertional thigh cramps. He described his urine turning to burgundy colour especially after prolonged exertion.

Investigations in the recent past had excluded presence of any significant ischaemic or inflammatory condition affecting his lower limbs.

On examination, pulse was 74 beats per minute, blood pressure was 122/66 mmHg, heart sounds were normal and there was no abnormal enlargement of any organ found on abdominal examination.

Investigations showed:

Serum urea 4.6 mmol/L (2.5-7.5)

Serum creatinine 88 µmol/L (60-110)

Serum corrected Calcium 2.32 mmol/L (2.2-2.6)

Serum Phosphate 0.92 mmol/L (0.8-1.4)

Serum creatine kinase 76 U/L (24-195)

Urine tested positive for myoglobin

What is the next most appropriate investigation?

- 1- Bone marrow examination for gaucher's cells
- 2- Kidney biopsy

- 3- Liver biopsy
- 4- Muscle biopsy
- 5- Urine for porphyrins

Answer & Comments

Answer: 4- Muscle biopsy

The exertional thigh cramps, the presence of myoglobin and change in colour of urine after exercise suggests glycogen storage disease, type V McArdle's syndrome.

The most appropriate investigation for this is muscle biopsy which reveals subsarcolemmal deposits of glycogen appearing at the periphery of fibres.

[Q: 3605] OnExamination 2012 - Basic Science

A 24-year-old man presented with exertional thigh cramps. He described his urine turning to burgundy colour especially after prolonged exertion.

Investigations in the recent past had excluded the presence of any significant ischaemic or inflammatory condition affecting his lower limbs.

On examination, his pulse was 74 beats per minute, blood pressure was 122/66 mmHg, heart sounds were normal and there was no abnormal enlargement of any organ found on abdominal examination.

Investigations revealed:

Serum urea 4.4 mmol/L (2.5-7.5)

Serum creatinine 88 mol/L (60-110)

Serum corrected Calcium 2.32 mmol/L (2.2-2.6)

Serum Phosphate 1.3 mmol/L (0.8-1.4)

Serum creatine kinase 88 U/L (24-195)

Urine testpositive for myoglobulin

What is the most likely diagnosis?

- 1- Acute intermittent porphyria

- 2- Alkaptonuria
- 3- Gaucher's disease
- 4- Glycogen storage disease
- 5- Multiple myeloma

Answer & Comments

Answer: 4- Glycogen storage disease

The exertional thigh cramps, the presence of myoglobin and change in colour of urine after exercise suggests glycogen storage disease type V - McArdle's syndrome.

[Q: 3606] OnExamination 2012 -
Dermatology

A 23-year-old obese female with known tuberculosis presents with ulcerating nodules on the back of her legs.

Which of the following is the most likely diagnosis?

- 1- Erythema induratum (EI)
- 2- Erythema marginatum
- 3- Erythema nodosum
- 4- Lupus pernio
- 5- Lupus vulgaris

Answer & Comments

Answer: 1- Erythema induratum (EI)

EI is a form of panniculitis characterised by chronic, recurrent, tender, subcutaneous, and sometimes ulcerated nodules on the lower legs that may also appear elsewhere.

Females are more frequently affected, with a female:male ratio of 7:1 and it is more frequent in younger females.

It is found in association with tuberculosis.

Erythema nodosum also a panniculitis is also commonly associated with tuberculosis and presents with painful erythematous nodules in recurrent crops over the legs and arms. The lesions however do not ulcerate.

Another possibility although not provided in the stems is pyoderma gangrenosum.

On the other hand, lupus vulgaris is a chronic, progressive and destructive form of cutaneous tuberculosis in patients with a moderate or high degree of immunity. It occurs more commonly in females than in males.

The classical lesions consist of reddish-brown plaques not nodules. The lesions progress by peripheral extension and central healing, atrophy and scarring. The areas of predilection

are head and neck (80%), followed by arms, legs, then trunk.

This rash is not the typical description of erythema marginatum (finer rash) or multiforme (blisters, targets).

Lupus pernio occurs in association with sarcoid.

[Q: 3607] OnExamination 2012 -
Dermatology

This 35-year-old woman developed this rash associated with facial swelling three weeks after she was started on oral carbamazepine for new-onset epilepsy.

She was also found to be febrile and had raised liver enzymes.

What treatment will she require?

- 1- High-dose oral corticosteroids
- 2- Intravenous immunoglobulins
- 3- Oral antibiotics
- 4- Oral anti-fungals
- 5- Topical corticosteroids

Answer & Comments

Answer: 1- High-dose oral corticosteroids

This patient has drug reaction with eosinophilia and systemic symptoms or DRESS syndrome.

It is a severe idiosyncratic drug reaction, characterised by a generalised erythematous rash often associated with facial oedema, involvement of internal organs (liver dysfunction), haematologic abnormalities (eosinophilia) and systemic illness (fever). It is treated with high dose oral corticosteroids for several months.

Option B: Intravenous immunoglobulins (IVIG) are not indicated in the treatment of DRESS syndrome. Some centres use IVIG for treatment of toxic epidermal necrolysis.

Option C: Oral antibiotics are not used to treat DRESS syndrome.

Option D: Oral anti-fungals are not indicated in the treatment of DRESS syndrome.

Option E: Topical corticosteroids are not useful in the treatment of DRESS syndrome.

[Q: 3608] OnExamination 2012 - Dermatology

This 35-year-old woman developed this rash associated with facial swelling three weeks after she was started on oral carbamazepine for new-onset epilepsy. She was also found to be febrile and had raised liver enzymes.

What is her diagnosis?

- 1- Angioedema
- 2- Drug reaction with eosinophilia and systemic symptoms (DRESS)
- 3- Fixed drug eruption
- 4- Toxic epidermal necrolysis
- 5- Viral exanthem

Answer & Comments

Answer: 2- Drug reaction with eosinophilia and systemic symptoms (DRESS)

This patient has DRESS syndrome, also known as drug hypersensitivity syndrome. It is a severe idiosyncratic drug reaction, characterised by a generalised erythematous rash often associated with facial oedema, involvement of internal organs (liver dysfunction), haematologic abnormalities (eosinophilia) and systemic illness (fever).

It is treated with high dose oral corticosteroids for several months. Common drugs implicated include the anti-epileptics, sulphur drugs and the penicillins.

Option A: Angioedema secondary to drug ingestion can also present with facial swelling but it occurs after a short latency period after

starting the drug. Patients may also have associated urticarial lesions.

Option C: Fixed drug eruption presents with one or several erythematous-to-dusky patches or plaques with central blister. It is not associated with systemic symptoms.

Option D: Toxic epidermal necrolysis is another severe idiosyncratic drug reaction that presents with extensive epidermal necrosis and mucosal involvement.

Option E: Viral exanthems may also present with a similar rash and systemic symptoms but a drug eruption is more likely in this case with the history of ingestion of oral anti-epileptics.

[Q: 3609] OnExamination 2012 - Dermatology

This child has this facial abnormality present since birth.

What other medical problems might she suffer from?

- 1- Aortic coarctation
- 2- Epilepsy
- 3- Liver haemangiomas
- 4- Posterior fossa abnormality
- 5- Renal artery stenosis

Answer & Comments

Answer: 2- Epilepsy

This patient has Sturge-Weber syndrome which presents with a facial port wine stain of the V1 +/- V2 or V3 segments. Other abnormalities include epilepsy, developmental delay and glaucoma.

Option A: Aortic coarctation is seen in PHACE syndrome which presents with segmental facial haemangioma, not a port wine stain.

Option C: Liver haemangiomas are seen in some patients with multiple cutaneous haemangiomas.

Option D: Posterior fossa abnormality, for example, Dandy-Walker malformation, is seen in patients with PHACE syndrome.

Option E: Renal artery stenosis is seen in neurofibromatosis.

[Q: 3610] OnExamination 2012 - Dermatology

A 16-year-old boy has severe inflammatory acne that has not responded to treatment with oral antibiotics. His dermatologist has decided to start him on oral isotretinoin.

Which of the following pairs of laboratory tests are required before and during treatment with oral isotretinoin?

- 1- Liver function tests and fasting lipid levels
- 2- Liver function tests and platelet levels
- 3- Platelet levels and serum electrolytes
- 4- Serum electrolytes and fasting lipid levels
- 5- Serum electrolytes and liver function tests

Answer & Comments

Answer: 1- Liver function tests and fasting lipid levels

Options B - E : These other pairs of laboratory tests are not required during treatment with oral isotretinoin.

[Q: 3611] OnExamination 2012 - Dermatology

A young male presented with multiple non-tender umbilicated papules in the suprapubic region and the scrotum.

What is the most likely diagnosis?

- 1- Folliculitis
- 2- Lichen planus
- 3- Molluscum contagiosum
- 4- Psoriasis
- 5- Verruca vulgaris

Answer & Comments

Answer: 3- Molluscum contagiosum

Option A: Folliculitis is a painful pustular eruption with follicular involvement.

Option B: Lichen planus presents as itchy violaceous polygonal papular lesions commonly over the ankles, wrists and low back.

Option D: Psoriasis presents as papulosquamous non-itchy plaques which exhibit micaceous scaling and usually occur over the extensors of the extremities.

Option E: Verruca vulgaris or common warts present as solitary or multiple painless skin lesions caused by human papillomavirus.

[Q: 3612] OnExamination 2012 - Dermatology

A young female presented with multiple non-tender, non-scaly, verrucous lesions on the leg and foot.

What is the most likely diagnosis?

- 1- Folliculitis
- 2- Lichen planus
- 3- Molluscum contagiosum
- 4- Psoriasis
- 5- Verruca vulgaris

Answer & Comments

Answer: 5- Verruca vulgaris

Option A: Folliculitis is a painful pustular eruption with follicular involvement.

Option B: Lichen planus presents as itchy violaceous polygonal papular lesions commonly over the ankles, wrists and low back.

Option C: Molluscum contagiosum presents usually as multiple umbilicated papules.

Option D: Psoriasis presents as papulosquamous non-itchy plaques which exhibit micaceous scaling and usually occur over the extensors of the extremities.

[Q: 3613] OnExamination 2012 - Dermatology

A patient presents with multiple vesicular lesions surrounded by erythema as shown following ingestion of sulfamethoxazole-trimethoprim.

What is the most likely diagnosis?

- 1- Erythema multiforme
- 2- Fixed drug eruption
- 3- Herpes zoster
- 4- Irritant contact dermatitis
- 5- Toxic epidermal necrolysis

Answer & Comments

Answer: 1- Erythema multiforme

Erythema multiforme classically presents as discrete vesicular or bullous lesions surrounded by a pale area and a ring of erythema. However all three zones may not always be evident. The eruption commonly follows the ingestion of the offending drug such as those belonging to the sulfa group.

Option B: Fixed drug eruption may present with sharply circumscribed pigmented macules, erythematous lesions or bullous lesions with a classical history of recurrence at the same site following the ingestion of the offending drug.

Option C: Herpes zoster presents as grouped vesicular eruptions on an erythematous base in dermatomal distribution.

Option D: Irritant contact dermatitis presents with acute onset vesicular eruptions at the site of contact of the irritant.

Option E: Toxic epidermal necrolysis is an acute dermatological emergency which

follows ingestion of offending drugs resulting in tender erythema and widespread bullae with subsequent skin necrosis and peeling.

[Q: 3614] OnExamination 2012 - Dermatology

A young HIV positive male presented with white discoloration of the nail plate.

What is the most likely diagnosis?

- 1- Candidal onychomycosis
- 2- Chronic paronychia
- 3- Irritant contact dermatitis
- 4- Pachyonychia congenita
- 5- Psoriatic nail dystrophy

Answer & Comments

Answer: 1- Candidal onychomycosis

Option B: Chronic paronychia presents with itchy painful swelling of the nail folds along with dystrophy of the nail plate.

Option C: Chronic exposure to irritants can lead to irregular buckling and dystrophy of the nail plate.

Option D: Pachyonychia congenita presents with dystrophic, thickened nails at or soon after birth along with palmoplantar keratoderma.

Option E: Psoriatic nail dystrophy presents with dystrophy of the nail plate, subungual hyperkeratosis, oil spots, onycholysis and splinter haemorrhages.

[Q: 3615] OnExamination 2012 - Dermatology

A 12-year-old child presents with an itchy rash around her ears which develops 24 to 48 hours after wearing earrings. She gives history of past episodes of similar complaints.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis

- 2- Folliculitis
- 3- Herpes zoster
- 4- Irritant contact dermatitis
- 5- Paederus dermatitis

Answer & Comments

Answer: 1- Allergic contact dermatitis

Option B: Folliculitis presents with painful papulopustular follicular lesions.

Option C: Herpes zoster presents with acute onset grouped vesicular eruptions in dermatomal distribution.

Option D: Irritant contact dermatitis presents with vesicular eruption at sites of contact with the irritant. The onset of eruption in irritant contact dermatitis is sudden, compared to allergic contact dermatitis which typically develops over 24 to 48 hours. A burning sensation rather than itching is the predominant symptom in irritant contact dermatitis.

Option E: Paederus dermatitis is an acute irritant contact dermatitis which presents as plaques, linear streaks or 'kissing' lesions at sites where the offending pederin from the crushed beetle comes into contact with the skin.

[Q: 3616] OnExamination 2012 - Dermatology

Which of the following suggests a diagnosis of molluscum contagiosum rather than chickenpox?

- 1- Absence of erythema surrounding lesions
- 2- Lesions disappearing within a month
- 3- Positive contact history
- 4- Presence of macules and papules
- 5- Presence of pruritis

Answer & Comments

Answer: 1- Absence of erythema surrounding lesions

Molluscum contagiosum is caused by a deoxyribonucleic acid (DNA) pox virus.

The lesions are small, skin coloured papules with central umbilication. There is little surrounding inflammation and they may be spread following scratching to other sites.

Chickenpox lesions in the early stages may be mistaken for molluscum. However, the presence of associated macules and later vesicles and pustules help to differentiate them.

These lesions also affect the mucus membranes, and usually disappear within a few weeks, while molluscum can persist for up to a year.

[Q: 3617] OnExamination 2012 - Dermatology

A 30-year-old farmer from a tropical country presented with painless swelling of his foot of six months duration. He volunteered a history of a trivial trauma while working his fields eight to nine months back.

Following the injury he noticed a gradually progressive painless swelling in the mid sole which subsequently discharged black grains from sinuses which developed over the swelling.

Plain radiograph revealed soft tissue swelling with a well preserved skeletal architecture.

What is the most likely diagnosis?

- 1- Folliculitis
- 2- Impetigo
- 3- Lupus vulgaris
- 4- Mycetoma foot
- 5- Osteomyelitis

Answer & Comments

Answer: 4- Mycetoma foot

Mycetoma foot caused by *Madurella mycetomatis* follows traumatic inoculation of the fungus mostly on the foot and the lower leg.

The earliest stage is a firm, painless nodule but, with time, papules, pustules which break down to form draining sinuses that appear on the skin surface following which the affected area becomes hard and swollen usually without significant pain extension to underlying bones and joints gives rise to periostitis, osteomyelitis and arthritis.

Advanced cases may present with destruction of bone within an infected area giving rise to gross deformities. There are usually multiple sinus tracts draining pus and granules. Lymph node involvement is rare.

Options A and B: The condition does not occur on the sole.

Option C: Lupus vulgaris usually presents with an indolent gradually progressive plaque with periods of activity and remission with atrophic scarring.

Option E: Osteomyelitis will reveal painful swelling, draining sinuses and skeletal involvement on plain radiograph.

[Q: 3618] OnExamination 2012 - Dermatology

A 16-year-old boy presents with scaly patches on his scalp.

Examination reveals well-circumscribed, circular areas of hair loss, 2-5 cm in diameter with scaling and raised margins. There is no scarring.

What is the most likely cause in this patient?

- 1- Discoid lupus erythematosus
- 2- Lichen planus
- 3- Morphea

4- Systemic lupus erythematosus

5- Tinea capitis

Answer & Comments

Answer: 5- Tinea capitis

This patient has non-scarring alopecia due to invasion of hairs by dermatophytes, most commonly *Trichophyton tonsurans*.

The most common causes of non-scarring alopecia include:

Telogen effluvium

Androgenetic alopecia

Alopecia areata

Tinea capitis

Traumatic alopecia.

Less commonly, non-scarring alopecia is associated with lupus erythematosus and secondary syphilis.

Scarring alopecia is more frequently the result of a primary cutaneous disorder such as:

Lichen planus

Folliculitis decalvans

Cutaneous lupus

Linear scleroderma (morphea).

[Q: 3619] OnExamination 2012 - Dermatology

A 22-year-old female returns from a fortnight holiday in Cyprus with a tan and numerous scaly hypopigmented lesions on the neck and upper trunk.

What is the most likely diagnosis?

- 1- Chronic plaque psoriasis
- 2- Discoid eczema
- 3- Pityriasis rosea
- 4- Pityriasis versicolor

5- Seborrhoeic dermatitis

Answer & Comments

Answer: 4- Pityriasis versicolor

Pityriasis versicolor is caused by a superficial fungal infection with *Pityrosporum ovale*.

It usually presents as slightly scaly hypopigmented lesions. Growth is encouraged by an increase in temperature and suntan oils, and is most commonly seen after a sun holiday.

Chronic plaque psoriasis, discoid eczema and seborrhoeic dermatitis have distinct appearance and distribution.

Pityriasis rosea usually starts with a herald patch followed by small scaly lesions following the rib lines.

[Q: 3620] OnExamination 2012 - Dermatology

A 70-year-old female presents with a four month history of a dry, pruritic rash affecting the upper back and shins.

What is the most appropriate initial management of this patient?

- 1- Avoidance of contact irritants
- 2- Emollients
- 3- Skin biopsy
- 4- Take a detailed history to ascertain contact allergen
- 5- Topical corticosteroids

Answer & Comments

Answer: 2- Emollients

This lady is likely to have asteatotic eczema which is a common problem and will improve just with plain emollients.

Xerotic skin is commoner in the elderly population especially in the winter months due to the dry heat from central heating.

All the other suggestions may be appropriate in a patient resistant to first line treatment but the first line is to try emollients.

[Q: 3621] OnExamination 2012 - Dermatology

A 17-year-old boy is diagnosed with scabies.

Which of the following statements regarding scabies is correct?

- 1- Is best treated by salicylate emulsion
- 2- It can be spread by a droplet infection
- 3- It causes itchiness in the skin even where there is no obvious lesion to be seen
- 4- It is caused by *Staphylococcus aureus*
- 5- Typically affects the face

Answer & Comments

Answer: 3- It causes itchiness in the skin even where there is no obvious lesion to be seen

Scabies is an infestation of the skin with the microscopic mite *Sarcoptes scabiei*. Infestation is common, found worldwide, and affects people of all races and social classes.

Scabies spreads rapidly under crowded conditions where there is frequent skin-to-skin contact between people, such as in hospitals, institutions, child-care facilities, and nursing homes.

Scabies can spread by direct, prolonged, skin-to-skin contact, with a person already infested with scabies. Contact must be prolonged (a quick handshake or hug will usually not spread infestation).

Infestation is easily spread to sexual partners and household members. Infestation may also occur by sharing clothing, towels, and bedding.

Scabies is characterised by papular-like irritations, burrows or rash of the skin, especially the webbing between the fingers;

the skin folds on the wrist, elbow, or knee; the penis, the breast, or shoulder blades.

A number of treatments are available for the treatment of scabies, including permethrin ointment, benzyl benzoate, and oral ivermectin for resistant cases. Antihistamines and calamine lotion may be used to alleviate itching.

[Q: 3622] OnExamination 2012 - Dermatology

A 60-year-old woman presents with raised, erythematous lesions on the limbs and blistering in the mouth and eyes. She had been taking a number of drugs prescribed by her GP.

Which may be responsible for her presentation?

- 1- Nifedipine
- 2- Paracetamol
- 3- Paroxetine
- 4- Prednisolone
- 5- Sulfasalazine

Answer & Comments

Answer: 5- Sulfasalazine

This is a typical case of Stevens-Johnson syndrome.

Stevens-Johnson syndrome (SJS) is an immune-complex-mediated hypersensitivity complex that is a severe expression of erythema multiforme. It is now known also as erythema multiforme major.

SJS typically involves the skin and the mucous membranes. While minor presentations may occur, significant involvement of:

Oral
Nasal
Eye

Vaginal

Urethral

Gastrointestinal (GI)

Lower respiratory tract mucous membranes may develop in the course of the illness.

GI and respiratory involvement may progress to necrosis.

SJS is a serious systemic disorder with the potential for severe morbidity and even death.

The drugs most closely associated with causing Stevens-Johnson syndrome are:

Antibacterials

Sulfonamides

Anticonvulsants (oxicam)

Non-steroidal anti-inflammatory agents (piroxicam and tenoxicam)

Chlormezanone

Allopurinol.

[Q: 3623] OnExamination 2012 - Dermatology

A 50-year-old man presented in the summer complaining of itching and blistering of his hands and forehead.

On examination there were small areas of excoriation on the backs of his hands.

What is the most likely diagnosis?

- 1- Dermatitis herpetiformis
- 2- Lupus erythematosus
- 3- Pemphigoid
- 4- Pemphigus
- 5- Porphyria cutanea tarda (PCT)

Answer & Comments

Answer: 5- Porphyria cutanea tarda (PCT)

The distribution of the lesions suggests a photosensitive element.

Both lupus erythematosus and PCT are associated with a photosensitive element, however this is more typical of PCT.

PCT causes blistering of the hands and the forehead which usually heal with small scar and milia formation.

It is also associated with an excessive alcohol intake.

[Q: 3624] OnExamination 2012 - Dermatology

Which of the following concerning pityriasis rosea is correct?

- 1- It is characterised by flat scaly patches
- 2- It is due to a fungal infection
- 3- It is frequently associated with oro-genital itching
- 4- May be preceded by intense itching
- 5- Tends to recur after apparent cure

Answer & Comments

Answer: 1- It is characterised by flat scaly patches

Pityriasis rosea is a rash that can occur at any age, but it occurs most commonly in people between the ages of 10 and 35 years.

It may be set off by a viral infection but does not appear to be contagious; herpes viruses 6 and 7 have most often been associated with pityriasis rosea. It is not caused by a fungus.

It is not related to foods, medicines, or stress. It most often affects teenagers or young adults.

The condition often begins as a large single pink patch on the chest or back. This patch may be scaly and is called a 'herald' or 'mother' patch.

Within a week or two, more pink patches, sometimes hundreds of them, appear on the body and on the arms and legs. Patches may also occur on the neck, and though rare, the face.

The oval patches follow the line of the ribs like a fir tree. They have a dry surface and may have an inner circlet of scaling.

[Q: 3625] OnExamination 2012 - Dermatology

A 75-year-old female presents with generalised erythema and pustule formation.

She has a history of psoriasis and has recently been treated with oral prednisolone for asthma.

What is the most appropriate next course of action?

- 1- Admission to hospital
- 2- Patch testing
- 3- Psoralen with ultraviolet-A therapy (PUVA)
- 4- Skin biopsy
- 5- Treatment with erythromycin as an outpatient

Answer & Comments

Answer: 1- Admission to hospital

This is erythroderma which is a dermatological emergency.

The patient needs admission with close supervision and supportive treatment with IV fluids and antibiotics.

[Q: 3626] OnExamination 2012 - Dermatology

A 45-year-old woman is admitted with a spiking temperature and sweats.

She has been unwell for the last three weeks with flitting arthralgia and lethargy. There is a rash over her trunk which is most prevalent in the mornings.

Blood cultures are sterile. Her recent transthoracic echocardiogram is normal. ESR is 56 mm/hour. Her ferritin is elevated at 6000 mg/l. Autoimmune screen is negative.

What is the likely diagnosis?

- 1- Adult onset Still's disease
- 2- Bacterial endocarditis
- 3- Meningitis
- 4- Rheumatoid arthritis
- 5- Systemic lupus erythematosus

Answer & Comments

Answer: 1- Adult onset Still's disease

Still's disease is a febrile syndrome in young adults (16-35 years) which affects multiple organs. The diagnosis is mainly one of exclusion.

The clinical features include:

High spiking fever (once a day, with return of temperature to normal)

Arthralgia/arthritis

Sore throat

Transient maculopapular rash (mildly pruritic in 1/3)

Lymphadenopathy

Hepatosplenomegaly and

Pleuritis/pericarditis.

Rarely there may be

Aseptic meningitis

Cranial nerve palsies

Iritis and

Peripheral neuropathy.

There is often delay in diagnosis.

Hyperferritinaemia (greater than five times normal) is present in 90% of cases.

[Q: 3627] OnExamination 2012 - Dermatology

A 12-year-old girl has severe atopic dermatitis which has not been well controlled with topical treatments, despite good compliance. Her dermatologist has decided to start her on treatment with oral ciclosporin.

Which of the following parameters needs to be regularly monitored while she is on treatment with ciclosporin?

- 1- Blood glucose levels
- 2- Blood pressure
- 3- Bone age
- 4- Height
- 5- Pubertal staging

Answer & Comments

Answer: 2- Blood pressure

Options A, C, D and E: These other parameters are not affected by ciclosporin therapy.

[Q: 3628] OnExamination 2012 - Dermatology

Deficiency of which one of the following trace elements is implicated as a cause of cardiomyopathy?

- 1- Chromium
- 2- Copper
- 3- Manganese
- 4- Selenium
- 5- Zinc

Answer & Comments

Answer: 4- Selenium

Selenium deficiency is one of the reversible causes of dilated cardiomyopathy.

[Q: 3629] OnExamination 2012 -
Dermatology

A young 3-month-old presented with a rash of two days' duration along lips, nose and adjacent right cheek.

The mother gave history of a short febrile illness preceding the rash. Past history of similar complaints was present.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Folliculitis
- 3- Hand, foot and mouth disease
- 4- Herpes simplex
- 5- Impetigo

Answer & Comments

Answer: 4- Herpes simplex

Herpes Simplex virus infection is common in children and in adolescents and is caused by two closely related virus types, type 1 and type 2. It commonly presents with recurrent painless grouped vesicles around mucocutaneous junctions such as the mouth and the nose. The first episode may be painful. Subsequent episodes present with mild discomfort with a history for per-eruption aura over the affected area. Management is largely symptomatic in recurrent episodes and topical 5% aciclovir cream may reduce discomfort. The case presented here reveals perinasal and perioral involvement typical of herpes simplex. Secondary impetiginization may be evident in some cases.

Option A: Allergic contact dermatitis will present with itchy papulo-vesicular eruption at the site of contact of the allergen.

Option B: Follicular involvement is evident in a case of painful papulopustular lesions. It is commoner in glabrous areas of the skin.

Option C: Hand, foot and mouth disease presents with vesicular and bullous lesions over palms, soles, buttocks and oral erosions. History of similar complaints may be present in contacts.

Option E: Superficial infection of the skin caused by *Staphylococcus aureus* and *Streptococcus pyogenes* is common in children. Impetigo classically involves the epidermis and presents with honey coloured crusts.

[Q: 3630] OnExamination 2012 -
Dermatology

A 30-year-old mother with her 6-year-old daughter presents with itching of the scalp with hair loss of one month duration.

Examination revealed patches of partial alopecia, sharply cut off circular in shape, with numerous broken-off, dull grey hairs in the alopecic patches.

Wood's lamp examination revealed green fluorescence.

What is the most likely diagnosis?

- 1- Alopecia areata
- 2- Seborrhoeic dermatitis
- 3- Secondary syphilis
- 4- Tinea capitis
- 5- Trichotillomania

Answer & Comments

Answer: 4- Tinea capitis

Tinea capitis or ringworm of the scalp is a common condition affecting children and uncommonly adults, where the adults are usually secondarily infected.

The response to this infection is variable, depending on the type of hair invasion, the level of host resistance and the degree of inflammatory host response. The appearance therefore may vary from a few dull grey,

broken-off hairs with a little scaling, detectable only on careful inspection, to a severe, painful, inflammatory mass covering most of the scalp. Itching is variable. Sharing of combs facilitates spread in the family.

Option A: Alopecia areata presents as non-itchy areas of hair loss with exclamation mark hairs.

Option B: Seborrhoeic dermatitis presents with diffuse greasy scaling. Hair loss in such localised patches is not a feature.

Option C: Secondary syphilis presents with moth-eaten alopecia.

Option E: Trichotillomania presents as patchy hair loss with hair of varying lengths in different as well as the same patch. Invariably there is a history of a family member having observed serial plucking of hair by the patient.

[Q: 3631] OnExamination 2012 - Dermatology

Which of the following is true regarding diabetic foot ulceration?

- 1- Autonomic neuropathy results in reduced peripheral blood flow
- 2- Callus formation at pressure areas is an important predictor of ulceration
- 3- Plantar ulceration is most commonly due to atherosclerosis
- 4- Skin infection is the most common initiating event in ulceration
- 5- Radiography can readily distinguish between Charcot's joint and osteomyelitis

Answer & Comments

Answer: 2- Callus formation at pressure areas is an important predictor of ulceration

Callus formation at pressure areas is an important predictor of potential ulceration.

Plantar ulceration is usually a consequence of neuropathy.

Minor skin trauma is probably the most common initiating event.

Studies have shown that autonomic neuropathy increases peripheral blood flow, probably as a result of reduced arteriovenous shunting.

It is difficult to distinguish radiographically between Charcot's joint and osteomyelitis, as neither have specific signs in their early stages.

[Q: 3632] OnExamination 2012 - Dermatology

A 59-year-old patient of South Asian origin presents with a widespread blistering rash.

Which of the following features would be consistent with a diagnosis of pemphigus?

- 1- Acanthosis
- 2- Blisters arising within the subepidermal area
- 3- IgA antibodies
- 4- Oral involvement
- 5- Treatment with methotrexate

Answer & Comments

Answer: 4- Oral involvement

Pemphigus is associated with loss of intercellular cohesion in the lower part of the epidermis, leading to acantholysis (separation of keratinocytes). Pemphigus is classically associated with flaccid blistering, and often with immunoglobulin (Ig)G antibodies.

Treatment may be successful with azathioprine.

Pemphigoid is associated with subepidermal bullae.

[Q: 3633] OnExamination 2012 - Dermatology

An 82-year-old lady had a history of a red

facial rash and has suffered with venous eczema of the legs. She was treated for acne rosacea.

On examination, she was noted to have blue-grey discolouration of both legs.

What drug is most likely to have caused this?

- 1- Amiodarone
- 2- Ciprofloxacin
- 3- Doxycycline
- 4- Minocycline
- 5- Oxytetracycline

Answer & Comments

Answer: 4- Minocycline

This patient has developed skin pigmentation of her legs as a side effect of treatment of her acne rosacea.

Tetracyclines are commonly used treatment for acne rosacea. Long-term use of minocycline in particular has been associated with non-dose dependent blue-grey pigmentation of skin in the lower legs, and mucosal pigmentation. This is more common in the elderly. On biopsy, intracellular pigment is seen in the dermis and the subcutaneous tissue and stains positively for melanin and iron. If not extensive, hyperpigmentation may partially regress after minocycline is discontinued. If it persists, alexandrite laser therapy can be effective.

Amiodarone can also cause a blue-grey slate discolouration of the skin, typically in sun exposed areas. You would therefore expect the face to be affected, and also amiodarone is not a treatment for acne rosacea which has been mentioned in this question to lead you to the correct answer.

Hypersensitivity to the sun has been described with ciprofloxacin, but discolouration as in this scenario is not recognised.

Oxytetracycline and doxycycline can lead to photosensitivity, but skin pigmentation seems to be specific to minocycline rather than a class effect of the tetracyclines.

[Q: 3634] OnExamination 2012 - Dermatology

A 35-year-old woman presents with a facial rash which had been present for one year.

On examination she had erythematous, scaly, indurated plaques on both cheeks with areas of scarring alopecia. Hyperkeratosis over dilated hair follicles was also seen.

What is the diagnosis?

- 1- Acne rosacea
- 2- Discoid lupus erythematosus
- 3- Impetigo
- 4- Lupus pernio
- 5- Psoriasis

Answer & Comments

Answer: 2- Discoid lupus erythematosus

The patient has discoid lupus as suggested by the indurated plaques on cheeks, the scarring alopecia and hyperkeratosis over the hair follicles.

[Q: 3635] OnExamination 2012 - Dermatology

A 74-year-old man with a thirty year history of psoriasis presented with generalised erythroderma of three days duration.

Examination reveals him to be shivering but otherwise well. He was treated as an inpatient with emollients and attention to fluid replacement and temperature control but failed to improve after five days.

What is the most appropriate next treatment?

- 1- Oral hydroxychloroquine
- 2- Oral methotrexate

- 3- Oral prednisolone
- 4- Topical coal tar
- 5- Topical Dithranol

Answer & Comments

Answer: 2- Oral methotrexate

Erythroderma is an emergency as patients are susceptible to profound dehydration, infection and hypothermia.

Methotrexate would be the only correct treatment for someone with erythrodermic psoriasis.

Steroids could lead to unstable pustular psoriasis and would not generally work.

Hydroxychloroquine has little effect on psoriasis.

Topical coal tar and Dithranol are good treatments for chronic plaque psoriasis but are highly irritant and would make the erythroderma much more inflamed and deteriorate his condition.

[Q: 3636] OnExamination 2012 - Dermatology

Which of the following is true of cutaneous anthrax?

- 1- Causes a black eschar which overlies pus
- 2- Is very likely to occur in subjects exposed to anthrax spores
- 3- Lesions are associated with marked oedema
- 4- Lesions are usually painful and tender
- 5- Mortality is approximately 20% despite antibiotic therapy

Answer & Comments

Answer: 3- Lesions are associated with marked oedema

Anthrax is caused by *Bacillus anthracis* a Gram positive rod.

Cutaneous anthrax is caused by direct contact of the bacteria into an open wound (usually touching an infected animal). Cutaneous anthrax is associated with a black eschar without pus, tends to be painless and to have widespread oedema.

Without antibiotics mortality is of the order of 20%, but with antibiotics, mortality is low, which contrasts with pulmonary anthrax.

[Q: 3637] OnExamination 2012 - Dermatology

Which of the following is aggravated by exposure to sunlight?

- 1- Acne vulgaris
- 2- Acute intermittent porphyria
- 3- Pellagra
- 4- Pseudoxanthoma elasticum
- 5- Psoriasis

Answer & Comments

Answer: 3- Pellagra

Exacerbation or localisation of other dermatoses is characteristic of:

- Pellagra
- Hartnup's disease
- Lupus erythematosus
- Darier's disease
- Rosacea
- Scleroderma
- Actinic lichen planus
- Lymphocytoma.

[Q: 3638] OnExamination 2012 - Dermatology

A 25-year-old woman has just been diagnosed with chronic cutaneous lupus erythematosus. She has no other clinical or laboratory

evidence to suggest systemic involvement. Apart from advice on sun avoidance, her dermatologist has decided to start her on oral hydroxychloroquine.

While on treatment with hydroxychloroquine, she requires pre-treatment evaluation and regular monitoring by which of the following specialists?

- 1- Cardiologist
- 2- Gastroenterologist
- 3- Haematologist
- 4- Neurologist
- 5- Ophthalmologist

Answer & Comments

Answer: 5- Ophthalmologist

Eye toxicity is one of the most serious side effects of treatment with antimalarials and requires regular screening. The cornea and macula may be affected by antimalarial medications.

Options A, B, C, and D : Regular monitoring by these specialists is not warranted for patients on treatment with antimalarials, although their services may be required in the event of the uncommon occurrence of systemic involvement of lupus in this patient.

[Q: 3639] OnExamination 2012 - Dermatology

A 3-year-old child is brought to you with a boggy swelling over the scalp with multiple pustules surmounting the swelling along with alopecia.

What is the most likely diagnosis?

- 1- Favus
- 2- Folliculitis
- 3- Impetigo
- 4- Kerion
- 5- Seborrheic dermatitis

Answer & Comments

Answer: 4- Kerion

Option A: Favus, a form of tinea capitis, presents with lesions characterised by yellow cup-shaped crusts termed scutula, which surround the infected hair follicles.

Option B: Folliculitis presents as painful follicular pustules.

Option C: Impetigo presents as vesiculobullous lesions or erosions covered with honey coloured crusts.

Option E: Seborrheic dermatitis is an itchy scalp condition presenting with greasy scaling.

Kerion presents with an inflammatory swelling on the scalp or the glabrous skin with numerous pustules in response to zoophilic fungi resulting in severe scarring alopecia in untreated cases.

[Q: 3640] OnExamination 2012 - Dermatology

An elderly male presented with dystrophic nail plates as shown along with an itchy rash of six months' duration on the adjacent areas of the fingers and both groins.

What is the most likely diagnosis?

- 1- Chronic Paronychia
- 2- Irritant contact dermatitis
- 3- Onychomycosis
- 4- Pachyonychia congenita
- 5- Psoriatic nail dystrophy

Answer & Comments

Answer: 3- Onychomycosis

Option A: Chronic paronychia presents with itchy painful swelling of the nail folds along with dystrophy of the nail plate.

Option B: Chronic exposure to irritants can lead to irregular buckling and dystrophy of the nail plate.

Option D: Pachyonychia congenita presents with dystrophic, thickened nails at or soon after birth along with palmoplantar keratoderma.

Option E: Psoriatic nail dystrophy presents with dystrophy of the nail plate, subungual hyperkeratosis, oil spots, onycholysis and splinter haemorrhages. Although it can involve the flexures such as the groin the rash is not itchy.

Dermatophyte fungal infection of the nail presents with Dystrophy of the affected nails. A moth eaten appearance as evident in the middle finger is characteristic. Commonly the affected individuals have evidence of dermatophytosis elsewhere, such as Tinea pedis, Tinea corporis, Tinea cruris (as in this case).

[Q: 3641] OnExamination 2012 - Dermatology

A middle aged female patient presented an anaesthetic plaque on the face of three months duration.

What is the most likely diagnosis?

- 1- Granuloma annulare
- 2- Hansen's disease
- 3- Sarcoidosis
- 4- Tertiary syphilis
- 5- Urticaria

Answer & Comments

Answer: 2- Hansen's disease

Option A: The localised form of granuloma annulare presents with annular or arcuate plaques. The margin may be continuous or consist of discrete papules coalescing together. Sensation is preserved.

Option C: Sarcoidosis may present with annular, arcuate lesions or papulosquamous lesions. Sensation is preserved.

Option D: Tertiary syphilis presents with nodular syphilide, papulosquamous lesions or gumma. Sensation is preserved.

Option E: Urticaria presents with recurrent wheals which usually subside in 24 hours. There is no sensory loss.

Hansen's disease, more commonly known as leprosy, is the correct option here. It classically produces reddish patches or hypopigmented areas of skin, with reduced sensation. These are required for the disease to be diagnosed.

[Q: 3642] OnExamination 2012 - Dermatology

A young child with a known case of plain warts on the face developed the shown linear distribution of the lesions.

What is this phenomenon called?

- 1- Auspitz' sign
- 2- Carpet tack sign
- 3- Gorlin sign
- 4- Koebner phenomenon
- 5- Raynaud's phenomenon

Answer & Comments

Answer: 4- Koebner phenomenon

Option A: Auspitz' sign is seen in psoriasis where the lesion upon scraping with a glass slide reveals pin-point bleeding on account of suprapapillary thinning of the epidermis.

Option B: Carpet tack sign - In discoid lupus erythematosus the removal of scale reveals multiple horny plugs on the under surface of the scale giving the appearance of carpet tacks.

Option C: Gorlin sign is the ability to touch the tip of the nose with the tongue seen in Ehlers-Danlos syndrome and some in the general population.

Option E: Raynaud's phenomenon is a vasospastic disorder characterised by vasospasms that decrease blood supply to the respective regions usually the hands and feet and infrequently the ear lobes, lips and nose. Cold is the classic trigger of the phenomenon.

[Q: 3643] OnExamination 2012 - Dermatology

A middle aged male farmer presented with multiple itchy inflammatory lesions over the chin. He volunteered a history of working at a cattle farm.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Carbuncle
- 3- Folliculitis
- 4- Kerion
- 5- Sycosis

Answer & Comments

Answer: 4- Kerion

Option A: Allergic contact dermatitis presents with itchy vesicular eruption at the site of contact with the allergen.

Option B: Carbuncle presents in a diabetic with a painful inflammatory swelling surmounted with multiple draining sinuses.

Option C: Folliculitis presents with painful follicular pustules.

Option E: Sycosis presents as subacute or chronic pyogenic infection involving the whole depth of the follicle.

[Q: 3644] OnExamination 2012 - Dermatology

A 5-year-old boy was brought in with crops of asymptomatic rash over the trunk of two months' duration.

Examination revealed skin coloured to pearly white and hemispherical to umbilicated papular lesions. Each one is approximately 4 mm in diameter and there are approximately 20 of these lesions present.

What is the most likely diagnosis?

- 1- Cutaneous cryptococcosis
- 2- Folliculitis
- 3- Herpes simplex
- 4- Molluscum contagiosum
- 5- Warts

Answer & Comments

Answer: 4- Molluscum contagiosum

Option A: HIV positive patients may present with cryptococcosis.

Cryptococcus neoformans infection affects 5-10% of patients with AIDS in the UK and USA and 30-40% in Africa. Up to 20% of patients with disseminated disease may have skin involvement.

In HIV/ AIDS cryptococcal skin involvement should be suspected when papulonodular necrotising skin lesions with central umbilication, like molluscum contagiosum are encountered in such patients along with pulmonary or neurological disease. Hence cutaneous cryptococcosis must be kept as a differential in a case of umbilicated lesions on the skin.

Option B: Folliculitis presents with painful papulopustular follicular lesions.

Option C: Herpes simplex infection presents with recurrent grouped vesicular eruptions on an erythematous base at mucocutaneous junctions.

Option E: Warts present with verrucous plaques and papules more commonly over extremities.

[Q: 3645] OnExamination 2012 - Dermatology

An 18-year-old woman attends antenatal clinic 12 weeks into her pregnancy where the doctor incidentally notes numerous small lumps over her trunk and freckles in her axillae.

She reported that none of her relatives had any similar features.

What is the most likely diagnosis?

- 1- Acanthosis nigricans
- 2- Dysplastic naevus syndrome
- 3- Mastocytosis
- 4- Neurofibromatosis
- 5- Tuberous sclerosis

Answer & Comments

Answer: 4- Neurofibromatosis

The patient is likely to have neurofibromatosis (NF1).

To be given the diagnosis of NF1, an individual must have at least two of the following features. Some people with NF1 have only two, while others can have several of these features:

Six or more café-au-lait spots, or coffee-coloured birthmarks, each measuring over an inch in adults (1/4 inch in children)

Two or more neurofibromas or a plexiform neurofibroma

Freckles under the arm or in the groin region

A tumour of the nerve to the eye called an optic glioma

Two or more spots on the iris of the eye called Lisch nodules

A problem of one of the bones such as bowing of a leg, with or without a fracture

A parent, brother, sister, or child with NF1.

[Q: 3646] OnExamination 2012 - Dermatology

This 8-year-old boy presents with a bizarre pattern of non-scarring hair loss which started about one year ago. He has no other systemic complaints.

On examination, you notice short hairs of different lengths within the areas of alopecia.

What is your most likely diagnosis?

- 1- Androgenetic alopecia
- 2- Alopecia areata
- 3- Secondary syphilis
- 4- Telogen effluvium
- 5- Trichotillomania

Answer & Comments

Answer: 5- Trichotillomania

Trichotillomania is more commonly seen in children and adolescents compared to adults. It is regarded as a primary psychiatric disorder and results from repetitive hair manipulation by the patient's own hands. It results in a patchy non-scarring alopecia that often has a bizarre distribution. Small, broken hairs of varying lengths may be seen within the patches of alopecia.

Option A: Androgenetic alopecia does not occur in the pre-pubertal age group.

Option B: Alopecia areata is a differential diagnosis to consider in patients presenting with trichotillomania. However, it usually does not lead to a 'bizarre' distribution and the patches of alopecia are usually 'clean' without short, broken, hairs of varying lengths.

Option C: Secondary syphilis may lead to a non-scarring alopecia with a 'moth-eaten'

appearance. However, it occurs in sexually active persons.

Option D: Telogen effluvium occurs one to three months after a major stress to the body, for example, illness, surgery, child birth. It leads to a diffuse form of non-scarring alopecia.

[Q: 3647] OnExamination 2012 - Dermatology

A 16-year-old boy presents with erythema nodosum.

Which of the following should be considered?

- 1- Cytomegalovirus infection
- 2- Kawasaki disease
- 3- Reiter's disease
- 4- Toxoplasmosis
- 5- Ulcerative colitis

Answer & Comments

Answer: 5- Ulcerative colitis

Erythema nodosum is characterised by painful, indurated, shiny, red, hot, elevated nodules 1-3 cm diameter particularly on the shins. There may be associated fever, malaise, and arthralgia ± hilar adenopathy.

Over a period of days they become violaceous, then dull purple, then fade like a large bruise without residual ulceration or scar. There may be crops over three to six weeks.

They are uncommon under the age of 6, and are commoner in females than males.

Causes include:

Infections

Bacteria: Streptococci, leptospirosis, cat-scratch disease, psittacosis, Yersinia.

Viruses: EBV.

Other

TB, tularaemia, histoplasmosis, coccidioidomycosis.

Drugs

Sulphonamides, oral contraceptive pill.

Systemic diseases

SLE, vasculitis, regional enteritis, ulcerative colitis, Behçet syndrome, sarcoidosis.

[Q: 3648] OnExamination 2012 - Dermatology

This 45-year-old man presents with these lesions on his face for the past three years. The lesions are worse after sun exposure.

A skin biopsy will reveal which of the following histological patterns?

- 1- Interface dermatitis
- 2- Intraepidermal bulla
- 3- Panniculitis
- 4- Spongiotic dermatitis
- 5- Subepidermal bulla

Answer & Comments

Answer: 1- Interface dermatitis

This patient has discoid lupus erythematosus. A skin biopsy will reveal interface dermatitis, characterised by basal vacuolar change, necrotic keratinocytes and pigment incontinence. This reaction represents damage to the epidermis from the inflammation.

Option B: An intraepidermal bulla is seen in intraepidermal blistering disorders, for example, pemphigus.

Option C: Panniculitis is inflammation of the subcutaneous fat and is seen classically in erythema nodosum.

Option D: Spongiotic dermatitis is the histological pattern seen in eczemas and other

papulosquamous disorders, for example, pityriasis rosea.

Option E: A subepidermal bulla is seen in subepidermal blistering disorders, for example, bullous pemphigoid.

[Q: 3649] OnExamination 2012 - Dermatology

A young female patient presented with an acute onset itchy rash on the face following the use of a new face cream for the first time.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Atopic dermatitis
- 3- Erythema multiforme
- 4- Herpes zoster
- 5- Irritant contact dermatitis

Answer & Comments

Answer: 5- Irritant contact dermatitis

Irritant contact dermatitis presents with an acute eczematous reaction with erythema, vesiculation, crusting and itching or a burning sensation at the site of the contact of the irritant. A sensitisation dose is not required as in allergic contact dermatitis.

Option A: Allergic contact dermatitis may present with an acute eczematous reaction at the site of contact with the allergen after a period of sensitisation.

Option B: Atopic dermatitis may present in the acute phase with an acute eczematous reaction on the face in infants. In adults the flexures are involved.

Option C: Erythema multiforme classically presents with target lesions with a central bullous lesion surrounded by an erythematous halo following the intake of an offending drug.

Option D: Herpes zoster presents with vesicobullous lesions in a dermatomal distribution.

[Q: 3650] OnExamination 2012 - Dermatology

A middle aged male presented with a lesion of six months' duration on his neck (as shown) with a history of recurrent episodes of pustulation and scarring.

Plain radiograph of the chest revealed non-homogenous opacities in both lungs.

What is the most likely diagnosis?

- 1- Lupus vulgaris
- 2- Miliary tuberculosis
- 3- Scrofuloderma
- 4- Squamous cell carcinoma
- 5- Tuberculous chancre

Answer & Comments

Answer: 1- Lupus vulgaris

Option A: because lupus vulgaris is a chronic, progressive form of cutaneous tuberculosis characterised commonly by annular plaques with areas of activity and scarring. Lesions may either appear as a result of endogenous spread of bacilli via haematogenous route from an endogenous focus such as pulmonary tuberculosis or at a site of exogenous direct inoculation. The lesion in the photograph represents one such classic lesion.

Option B: Miliary tuberculosis manifests as disseminated erythematous macules, papules as well as purpuric lesions, due to haematogenous spread in a patient with tuberculosis.

Option C: Scrofuloderma presents initially as a subcutaneous nodule which later breaks down to represent skin ulceration over an underlying area of tuberculous focus such as a lymph node, bone or joint.

Option D: Squamous cell carcinoma typically arises from an unhealthy skin usually in areas of chronic photo-damage as an indurated scaly and fissured plaque.

Option E: Tuberculous chancre presents initially as an inflammatory papule at the site of inoculation which later breaks down into a non-healing, shallow, undermined ulcer with a granulomatous base followed by painless regional lymphadenopathy.

[Q: 3651] OnExamination 2012 - Dermatology

A middle aged male presented with dystrophic nail plates as shown with an itchy rash of six months' duration in both groins.

What is the most likely diagnosis?

- 1- Chronic paronychia
- 2- Irritant contact dermatitis
- 3- Onychomycosis
- 4- Pachyonychia congenita
- 5- Psoriatic nail dystrophy

Answer & Comments

Answer: 3- Onychomycosis

Option A: Chronic paronychia presents with itchy painful swelling of the nail folds with dystrophy of the nail plate.

Option B: Chronic exposure to irritants can lead to irregular buckling and dystrophy of the nail plate.

Option D: Pachyonychia congenita presents with dystrophic, thickened nails at or soon after birth along with palmoplantar keratoderma.

Option E: Psoriatic nail dystrophy presents with dystrophy of the nail plate, subungual hyperkeratosis, oil spots, onycholysis and splinter haemorrhages. Although it can involve the flexures such as the groin the rash is not itchy.

[Q: 3652] OnExamination 2012 - Dermatology

A middle aged male with a known case of bronchial asthma presented with recurrent episodes of itching, vesiculation and oozing over the cubital fossae and popliteal fossae.

What is his diagnosis?

- 1- Atopic dermatitis
- 2- Dermatitis herpetiformis
- 3- Impetigo
- 4- Irritant contact dermatitis
- 5- Pemphigus vulgaris

Answer & Comments

Answer: 1- Atopic dermatitis

Option B: Dermatitis herpetiformis is an autoimmune blistering disorder associated with a gluten-sensitive enteropathy. Dermatitis herpetiformis is characterised by extensor involvement with grouped excoriations, papulovesicular eruptions and urticarial lesions.

Option C: Impetigo presents in children with painful bullous lesions with honey coloured crusts.

Option D: Irritant contact dermatitis presents with vesicular eruption at sites of contact with the irritant, often on the exposed areas such as extremities. A burning sensation is common as opposed to the itching experienced in allergic contact dermatitis.

Option E: Pemphigus vulgaris presents with vesiculobullous lesions and erosions on normal-appearing skin.

[Q: 3653] OnExamination 2012 - Dermatology

A middle aged male presented with sudden onset non-tender annular erythematous plaques with pustulation.

He had been managed with systemic steroids in the recent past for an acute exacerbation of bronchial asthma. He gave a history of recurrent episodes of scaly plaques in the past.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Folliculitis
- 3- Pemphigus vulgaris
- 4- Pustular psoriasis
- 5- Subcorneal pustular dermatosis

Answer & Comments

Answer: 4- Pustular psoriasis

Option A: Allergic contact dermatitis will present with itchy papulo-vesicular eruption at the site of contact of the allergen.

Option B: Folliculitis presents with painful folliculocentric pustules.

Option C: Pemphigus vulgaris presents with vesiculobullous lesions and erosions on normal appearing skin.

Option E: Subcorneal pustular dermatosis occurs mainly in flexures and on the flexor aspect of the limbs. It presents with characteristic pustules, with pus which accumulates in the lower half of a fully developed pustule, leaving clear fluid in the upper half. Pustules may coalesce, forming annular or serpiginous patterns with a scaly edge. The eruption fades to leave faint hyperpigmentation and successive such episodes may occur.

[Q: 3654] OnExamination 2012 - Dermatology

A 2-year-old child presented with multiple (more than three) hypopigmented lesions on the anterior chest wall and trunk since the age of one year. Parents volunteered a history of recurrent seizures.

Examination also revealed few rubbery pinkish plaques on the low back.

What is the most likely diagnosis of the hypopigmented lesions?

- 1- Ash leaf macule
- 2- Hansen's disease
- 3- Nevus depigmentosus
- 4- Pityriasis alba
- 5- Vitiligo

Answer & Comments

Answer: 1- Ash leaf macule

Option B: Hansen's disease presents uncommonly at this age. Skin manifestations include hypopigmented macules which may be hypo-anaesthetic to normo-anaesthetic depending on the spectrum of the disease, along with plaques in the tuberculoid pole which would be hypo-anaesthetic.

Option C: Nevus depigmentosus and option E, vitiligo, present with depigmented lesions.

Option D: Pityriasis alba: the individual lesions are rounded, oval or irregular hypopigmented macules which are usually not well margined.

The lesions are often slightly erythematous and have fine scaling. The initial erythema subsides leaving only persistent fine scaling and hypopigmentation.

[Q: 3655] OnExamination 2012 - Dermatology

A 12-year-old child presents with the above depressed sclerotic linear lesion over the right frontoparietal scalp of five years duration. There is a history of initial progression and thereafter a static phase for the past two years.

Radiographs and neuroimaging reveal no abnormal findings. There is no history of

seizures or any history of neurological involvement.

What should be the first line of management?

- 1- High dose IV methylprednisolone
- 2- No active management
- 3- Prophylactic anti-epileptics
- 4- Systemic corticosteroids
- 5- Urgent surgery

Answer & Comments

Answer: 2- No active management

En coup de sabre, a variant of scleroderma is characterised by a linear, atrophic depression affecting the frontoparietal aspect of the face and scalp, suggestive of a stroke from a sword, as shown in the image. Such lesions may extend into the underlying tissues. Scalp involvement results in scarring alopecia.

Option A and Option D: Emergent measures in the absence of active disease progression or neuro-ocular complications are not indicated.

Option C: Prophylactic anti-epileptics have no role as the case has had no history of seizures, neuroimaging is normal and the condition is not progressing.

Option E: Surgery has no role presently.

*The management of this case is controversial. Some paediatric dermatologists may give a trial of methotrexate, as the disease may still be slowly progressing and treatment may prevent worsening cosmetic disfigurement.

[Q: 3656] OnExamination 2012 - Dermatology

A middle aged lady working in a restaurant kitchen presented with swelling of her right thumb of two months duration.

What is the most likely diagnosis?

- 1- Acute paronychia

- 2- Candidal paronychia
- 3- Dermatophytosis
- 4- Ingrowing toe nail
- 5- Pustular psoriasis

Answer & Comments

Answer: 2- Candidal paronychia

Option A: Acute paronychia is an acute tender inflammatory swelling of the nail folds caused by Staphylococcus aureus commonly.

Option C: Dermatophytosis presents with onychomycosis with a moth eaten appearance of the nail plate.

Option D: Ingrowing toe nail presents with acute onset inflammation of the affected digit with the distal corner of the nail plate buried in the lateral nail fold.

Option E: Pustular psoriasis variant acrodermatitis continua of

Hallopeau or parakeratosis pustulosa affects the nail plate which may be lifted by sterile pustules with associated erythema and discomfort and subsequent nail loss.

[Q: 3657] OnExamination 2012 - Dermatology

A young male presented with multiple nodulocystic lesions and comedones over the face.

What is the most likely diagnosis?

- 1- Acne
- 2- Folliculitis
- 3- Hidradenitis suppurativa
- 4- Pyoderma faciale
- 5- Sycosis barbae

Answer & Comments

Answer: 1- Acne

Option B: Folliculitis is a painful pustular eruption with follicular involvement.

Option C: Hidradenitis suppurativa presents as tender erythematous papules, abscesses and dermal contractures in the apocrine gland bearing areas of the skin such as the axillary regions.

Option D: Pyoderma faciale a rare complication of rosacea presents with multiple nodules, abscesses and sinus tracts along with systemic signs. Comedones are absent.

Option E: Sycosis barbae presents as painful pustular eruptions in the glabrous areas of the skin.

[Q: 3658] OnExamination 2012 - Dermatology

A 17-year-old man comes to the clinic. He has recently returned from a holiday to Spain with his friends and is very disappointed with the quality of his tan, as there appear to be large depigmented areas on the skin of his abdomen and on his back. He says the areas are itchy.

On examination you confirm the depigmentation, and there is superficial scaling over the areas.

Which of the following is the most appropriate treatment?

- 1- Oral antifungals
- 2- Oral corticosteroids
- 3- Reassurance
- 4- Topical antifungals
- 5- Topical corticosteroids

Answer & Comments

Answer: 4- Topical antifungals

This patient has clinical findings which are typical of those seen in pityriasis versicolor, caused by a fungus known as Malassezia

furfur. This causes more of a problem in hot weather, is present on the skin of the trunk, and leads to the depigmentation seen here.

Topical antifungals are the treatment of choice; if the depigmentation is extensive, a systemic compound like fluconazole may be used.

[Q: 3659] OnExamination 2012 - Dermatology

A 45-year-old man is referred to the dermatology clinic, with an intensely itchy, red, scaling rash which affects his scalp predominantly and is worse in spring and winter time. He also has a patch on his chest and around his beard.

On examination he has a severe scalp rash with crusting and scaling of skin.

Investigations show

Haemoglobin 13.1 g/dl (13.5-18)

White cell count $5.9 \times 10^9/L$ (4-10)

Platelets $192 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 101 $\mu\text{mol/l}$ (60-120)

Scalp biopsy Hyperkeratosis, acanthosis and focal spongiosis

He tells you he cares most about his scalp.

Which of the following is the most appropriate first line treatment for him?

- 1- Coal tar shampoo
- 2- Ketoconazole shampoo
- 3- Oral prednisolone
- 4- Tacrolimus ointment
- 5- Topical betamethasone

Answer & Comments

Answer: 2- Ketoconazole shampoo

This man has seborrhoeic dermatitis which tends to affect hair bearing areas of skin with the scalp the worst affected.

It is thought that, at least in part, the activity of activated T cells may be enhanced by an increased reservoir of Malassezia yeasts. As such, regular washing of the hair with a ketoconazole based shampoo has been shown to reduce the severity of the condition.

Topical corticosteroids have been shown to hasten recovery, but may be associated with a rebound effect and rapid recurrence of the rash when they are withdrawn.

Coal tar shampoo and topical tacrolimus are alternate treatments.

Asteatotic dermatitis typically presents in the elderly with pruritic, xerotic, scaly skin typically over the shins but may occur over the back and hands. Tar based preparations are never used as they would aggravate the condition.

[Q: 3660] OnExamination 2012 - Dermatology

A 31-year-old woman comes to the dermatology clinic complaining that a mole on her forearm has changed shape, enlarging to nearly three quarters of a centimetre in diameter, and although it was previously homogeneous in colour, parts of it have now become a very dark black.

She has no significant past medical history but admits to significant use of tanning beds and having spent a few years living in California.

Investigations show:

Haemoglobin 13.0 g/dl(13.5-18)

White cell count $5.4 \times 10^9/L$ (4-10)

Platelets $200 \times 10^9/L$ (150-400)

ESR 11 mm/hr(1-20)

Sodium 139 mmol/l (134-143)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (60-120)

Excision biopsy: 5 mm thick lesion, no ulceration.

Which of the following features is most associated with a poor prognosis in this patient?

- 1- Depth of the melanoma lesion
- 2- Female sex
- 3- Her age
- 4- Lack of ulceration
- 5- Significant exposure to sun beds

Answer & Comments

Answer: 1- Depth of the melanoma lesion

Survival is strongly correlated with depth of melanoma at the point of diagnosis, with lesions over 4 mm thick being associated with a particularly poor outcome.

Other predictors of a poor outcome include increasing age and male sex.

Ulceration of the lesion also implies greater risk of metastases. For lesions over 4 mm thick with ulceration, five year survival is less than 50%.

[Q: 3661] OnExamination 2012 - Dermatology

A 45-year-old teacher presents six weeks after he returns from a hiking holiday in South America with a shallow, painless ulcer of the nose.

What is the likely diagnosis?

- 1- Fusobacterium ulcerans
- 2- Leishmaniasis
- 3- Squamous cell carcinoma
- 4- Trichomoniasis
- 5- Trypanosomiasis

Answer & Comments

Answer: 2- Leishmaniasis

The likely diagnosis, given the history, is cutaneous leishmaniasis. Lesion pain and pruritis may be present in cutaneous leishmaniasis, but are not typical.

Diagnosis is by histologic section with staining for amastigotes. *Leishmania braziliensis* is the likely pathogen which is spread by sandfly bites in endemic areas.

Fusobacteria cause the tropical ulcer, an intensely painful, shallow ulcer.

[Q: 3662] OnExamination 2012 - Dermatology

A 41-year-old female presents with a six month history of a pruritic vesicular-papular rash on the elbows, knees and buttocks associated with numerous blistering eruptions and excoriations.

Her GP has prescribed topical steroid therapy but this has not helped.

What is the most likely diagnosis?

- 1- Atopic eczema (dermatitis)
- 2- Dermatitis herpetiformis (DH)
- 3- Lichen planus
- 4- Psoriasis
- 5- Scabies

Answer & Comments

Answer: 2- Dermatitis herpetiformis (DH)

This patient presents with pruritic vesicles on her elbows, knees and buttocks which have not responded to topical steroids. This is the classical presentation of DH.

Atopic dermatitis usually is flexural and responds to topical steroids.

Henoch-Schönlein purpura is a form of vasculitis.

In scabies there are burrows and in psoriasis the rash consists of plaques with silvery scales.

[Q: 3663] OnExamination 2012 - Dermatology

A 24-year-old female attends clinic complaining of numerous depigmented areas on the arms and legs.

Which of the following diseases is most likely to accompany this skin condition?

- 1- Addison's disease
- 2- Hypoparathyroidism
- 3- Pernicious anaemia
- 4- Systemic lupus erythematosus
- 5- Tuberous sclerosis

Answer & Comments

Answer: 3- Pernicious anaemia

The suggested diagnosis is vitiligo which is associated with numerous autoimmune conditions including, in order of frequency:

Autoimmune hypothyroidism

Pernicious anaemia

Alopecia areata

Addison's disease.

It is associated with both type 1 and 2 autoimmune polyendocrine syndromes but these are much rarer than the former diagnoses.

[Q: 3664] OnExamination 2012 - Dermatology

A 55-year-old woman presents with a non-pruritic rash that had developed over the last two months. Examination revealed several, circular, erythematous, raised, smooth-surfaced lesions of variable size from 1-5 cm in diameter on the elbows, extensor aspects of the forearms and knuckles.

What is the most likely diagnosis?

- 1- Eczema
- 2- Granuloma annulare
- 3- Psoriasis
- 4- Tinea corporis
- 5- Urticaria

Answer & Comments

Answer: 2- Granuloma annulare

The history of non-itchy, circular, raised, smooth-surfaced lesions on the elbows, extensor aspects of the forearms and knuckles and the raised borders are suggestive of granuloma annulare.

Discoid eczema tends to be scaly and pruritic in nature.

Psoriasis typically has a silvery scale and can be pruritic.

Urticaria lasts a few hours and is pruritic.

Tinea corporis is a fungal infection and is typically scaly and pruritic in nature.

The most likely answer is therefore granuloma annulare. This can be associated with diabetes.

[Q: 3665] OnExamination 2012 - Dermatology

A 68-year-old woman presents with a two month history of a widespread pruritic rash.

Examination reveals widespread erythema with several small blisters containing straw-coloured fluid and one or two larger serosanguineous blisters.

What is the most likely diagnosis?

- 1- Bullous impetigo
- 2- Bullous pemphigoid
- 3- Insect bite
- 4- Scabies

- 5- Urticarial vasculitis

Answer & Comments

Answer: 2- Bullous pemphigoid

Pemphigoid, erythema multiforme and herpes are the commonest causes of a blistering rash.

The history above is a classic description of bullous pemphigoid (BP).

Immunoglobulin (Ig)G autoantibodies bind to the skin basement membrane in patients with BP. The binding of antibodies at the basement membrane activates complement and inflammatory mediators.

Activation of the complement system is thought to play a critical role in attracting inflammatory cells to the basement membrane. These inflammatory cells are postulated to release proteases, which degrade hemidesmosomal proteins and lead to blister formation.

Eosinophils are characteristically present in blisters as demonstrated by histopathologic analysis, although their presence is not an absolute diagnostic criterion.

[Q: 3666] OnExamination 2012 - Dermatology

Which statement regarding tinea capitis is correct?

- 1- It causes patches that fluoresce dull green under Wood's lamp
- 2- It is effectively treated with topical nystatin ointment
- 3- It is most commonly caused by the fungus Trichophyton tonsurans
- 4- It often results in permanent alopecia
- 5- Its presence should suggest immunological deficiency

Answer & Comments

Answer: 3- It is most commonly caused by the fungus *Trichophyton tonsurans*

Tinea capitis is a dermatophyte infection of the scalp. There are a number of causative organisms, but currently in the UK and USA is most often caused by *Trichophyton tonsurans*, and occasionally by *Microsporum canis*. It is commonest in areas of socio-economic deprivation.

There is initially a small papule at the base of the hair follicle which spreads peripherally forming a scaly circular plaque (ringworm) within which there are brittle, broken infected hairs (exclamation mark hairs).

Confluent patches of alopecia develop and there may be pruritis. Sometimes a severe inflammatory response produces an elevated boggy granulomatous mass (kerion), studded with sterile pustules. There may be fever and regional lymphadenopathy, and occasionally permanent scarring and alopecia may result.

The crusted patches fluoresce dull green under Wood's light if caused by *Microsporum canis*, but do not fluoresce if caused by *Trichophyton tonsurans*. Microscopic examination of a potassium hydroxide (KOH) preparation shows tiny spores and the fungi may be grown in Sabouraud medium with antibiotics.

Oral griseofulvin for two to three months is required, or ketoconazole for resistant cases.

[Q: 3667] OnExamination 2012 - Dermatology

Which of the following concerning leg ulcers is correct?

- 1- Diuretics have been shown to improve ulcer healing when associated with oedema
- 2- In diabetic ulcers, the dressing should be left in situ for no more than one week
- 3- Large gravitational ulcers are always painful

- 4- Treating superficial infection with antibiotics has been shown to be beneficial
- 5- Ulcers caused by arterial disease are typically treated by compression bandaging

Answer & Comments

Answer: 2- In diabetic ulcers, the dressing should be left in situ for no more than one week

Diuretics may reduce oedema but have not been demonstrated per se to reduce healing time.

Gravitational ulcers are not usually painful.

If there are no obvious features of surrounding cellulitis, antibiotic therapy is usually unnecessary and has not been shown to improve healing in superficial infection which is common in ulceration.

[Q: 3668] OnExamination 2012 - Dermatology

A 21-year-old soldier presented with an itchy rash of two weeks' duration affecting his hands, feet, groins and buttocks. The rash was typically more itchy at night. The patient gave a history of his dormitory colleagues suffering from similar complaints.

Examination revealed numerous excoriated papules and burrows primarily localised to the web spaces of hands and feet as well as the natal cleft.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Dermatophytosis
- 3- Folliculitis
- 4- Impetigo
- 5- Scabies

Answer & Comments

Answer: 5- Scabies

Scabies is common in children and young adults, occurring more commonly in places where crowding facilitates transmission of the mite. The rash causes itching more during the nights when the patient is warmer. Areas of skin scarce in pilosebaceous follicles are the preferred site by the scabies mite.

Option A: Allergic contact dermatitis will present with itchy papulo-vesicular eruption at the site of contact of the allergen.

Option B: Dermatophytosis usually presents with annular scaly plaques with active peripheral margins and central clearing. The lesions are typically itchy and increase in number over a period of time.

Option C: Folliculitis presents with erythematous follicular papules and pustules.

Option D: Impetigo is a superficial infection of the skin common in children. It classically involves the epidermis and presents with honey coloured crusts. It is contagious and spreads among contacts as well as by autoinoculation.

[Q: 3669] OnExamination 2012 - Dermatology

A 43-year-old woman with atopic dermatitis (atopic eczema) presented with an acute generalised exacerbation of her disease.

She was admitted to hospital but failed to improve with emollients, topical betamethasone 17-valerate and oral antihistamine.

Which one of the following drugs is the most appropriate treatment?

- 1- Acitretin
- 2- Amoxicillin
- 3- Colchicine
- 4- Cyclosporin
- 5- Dapsone

Answer & Comments

Answer: 4- Cyclosporin

Cyclosporin is a well used drug in the treatment of atopic dermatitis (AD). It is usually at doses of 2-5 mg/kg.

The pathophysiology of AD is complex but the T lymphocytes are involved and it is known that there is an increased production of cytokines particularly IL-4.

Cyclosporin is a suppressor of T cells and in that respect works very well in atopic dermatitis and psoriasis. The side effects of hypertension and renal toxicity limit its use.

These patients are seen monthly to have their blood pressure and urea and electrolytes checked.

[Q: 3670] OnExamination 2012 - Dermatology

An elderly patient presented with an acute onset painful rash (above) on the face.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Atopic dermatitis
- 3- Erythema multiforme
- 4- Herpes zoster
- 5- Irritant contact dermatitis

Answer & Comments

Answer: 4- Herpes zoster

Herpes zoster presents with grouped vesicobullous lesions in a dermatomal distribution.

Option A: Allergic contact dermatitis may present with an acute eczematous reaction at the site of contact with the allergen after a period of sensitisation.

Option B: Atopic dermatitis may present in the acute phase with an acute eczematous

reaction on the face in infants. In adults the flexures are involved.

Option C: Erythema multiforme classically presents with target lesions with a central bullous lesion surrounded by an erythematous halo following the intake of an offending drug.

Option E: Irritant contact dermatitis presents with an acute eczematous reaction with erythema, vesiculation, crusting and itching or a burning sensation at the site of the contact of the allergen. A sensitisation dose is not required as in allergic contact dermatitis.

[Q: 3671] OnExamination 2012 - Dermatology

A middle aged male with diabetes presented with a tender lesion (as shown) over his buttock of two days' duration.

What is the most likely diagnosis?

- 1- Carbuncle
- 2- Ecthyma
- 3- Folliculitis
- 4- Impetigo
- 5- Sycosis

Answer & Comments

Answer: 1- Carbuncle

Option B: Ecthyma usually follows trivial trauma such as a scratch or insect bite on the legs and develops into a small pustular lesion on an erythematous base, with an adherent hard crust of dried exudate below which ulceration exists.

Option C: Folliculitis presents with erythematous painful follicular pustules.

Option D: Superficial infection of the skin caused by *Staphylococcus aureus* and *Streptococcus pyogenes* is common in children. Impetigo classically involves the epidermis and presents with honey coloured

crusts. It is contagious and spreads among contacts as well as by autoinoculation.

Option E: Sycosis barbae presents clinically with inflammatory folliculo-centric pustules commonly on the glabrous areas of the skin.

[Q: 3672] OnExamination 2012 - Dermatology

A 3-month-old infant presented to the dermatologist with a red lesion over the left side of the face. It was flat initially at birth and had progressively become elevated and boggy.

What is the most likely diagnosis?

- 1- Aplasia cutis
- 2- Cystic hygroma
- 3- Haemangioma
- 4- Squamous cell carcinoma
- 5- Lymphangioma

Answer & Comments

Answer: 3- Haemangioma

Option A: Aplasia cutis presents with congenital absence of skin.

Option B: Cystic hygroma is a congenital multiloculated lymphatic lesion that is classically found in the left posterior triangle of the neck. This is the most common form of lymphangioma which typically transilluminates and is bluish in colour.

Option D: Squamous cell carcinoma most commonly presents in the middle aged and elderly as keratotic plaques in the sun exposed areas.

Option E: Lymphangioma of the head and neck region involves swelling or mass that is soft to palpation and well circumscribed or diffuse. It may be well to ill-defined and is often associated with a bluish discoloration. See cystic hygroma above.

[Q: 3673] OnExamination 2012 - Dermatology

A 5-year-old boy was brought with pigmentation around his mouth and oral mucosa of six months duration.

What is the most likely diagnosis?

- 1- Condylomata lata
- 2- Congenital melanocytic naevus
- 3- Freckles
- 4- Mucosal lichen planus
- 5- Peutz-Jegher's syndrome

Answer & Comments

Answer: 5- Peutz-Jegher's syndrome

Option A: Condylomata lata - in secondary syphilis, condylomata

lata appear as flat-topped warty papules, affecting the mucosa. Oral mucosa are rarely affected.

Option B: Congenital melanocytic naevus presents with naevi of varying sizes at birth.

Option C: Freckles present as brownish macules on sun exposed sites and do not affect the mucosa.

Option D: Mucosal lichen planus commonly presents as bilateral, white lesions in the buccal and lingual mucosa. They may be reticular, papular or plaque-like or may have a violaceous hue.

Mucocutaneous pigmentation and hyperpigmented macules typically occur in Peutz-Jeghers syndrome. They appear as small brown or dark blue spots as lentigenes, most commonly in the peribuccal area and buccal mucosa. The pigmentation in perioral region often crosses the vermillion border and can extend to the perinasal area too. Peutz Jeghers syndrome is associated with gastrointestinal polyposis.

[Q: 3674] OnExamination 2012 - Dermatology

A 1-month-old otherwise healthy baby presented with a rash on the scalp with greasy scaling.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Cradle cap
- 3- Folliculitis
- 4- Impetigo
- 5- Tinea capitis

Answer & Comments

Answer: 2- Cradle cap

Option A: Allergic contact dermatitis will present with itchy papulovesicular eruption at the site of contact of the allergen.

Option C: Folliculitis presents with obvious follicular involvement in a case of painful papulopustular lesions. It is commoner in glabrous areas of the skin.

Option D: Impetigo, a superficial infection of the skin caused by Staphylococcus aureus and Streptococcus pyogenes is common in children. Impetigo classically involves the epidermis and presents with honey coloured crusts.

Option E: Tinea capitis or ringworm of the scalp is a common condition affecting children and uncommonly adults. The appearance varies from a few dull grey, broken-off hairs with a little scaling, detectable only on careful inspection, to a severe, painful, inflammatory mass covering most of the scalp. Itching is variable.

[Q: 3675] OnExamination 2012 - Dermatology

An HIV positive male presented with whitish discolouration of tongue and oral mucosa.

What is the most likely diagnosis?

- 1- Aphthous stomatitis
- 2- Geographical tongue
- 3- Herpetic gingivostomatitis
- 4- Mucosal candidiasis
- 5- Mucosal lichen planus

Answer & Comments

Answer: 4- Mucosal candidiasis

Option A: Aphthous stomatitis is also common in HIV positive and manifests with recurrent ulceration of the oral mucosa.

Option B: Geographical tongue manifests as apparent bald areas of the tongue.

Option C: Herpetic gingivostomatitis presents as painful erosions of the oral mucosa and gingiva.

Option E: Mucosal lichen planus may present with white to violaceous macules and plaques over the oral mucosa. The lesions cannot be scraped off.

[Q: 3676] OnExamination 2012 - Dermatology

A young male athlete presented with multiple itchy scaly lesions over his legs and thighs. Historically he had had similar lesions in the past which had been treated with unspecified local medications.

On examination he was found to have multiple erythematous scaly plaques with a raised peripheral margin, a clear centre with hyper-pigmentation.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Fixed drug eruption
- 3- Psoriasis
- 4- Sarcoidosis
- 5- Tinea corporis

Answer & Comments

Answer: 5- Tinea corporis

Dermatophytosis is common in athletes. It usually presents with annular scaly plaques with active peripheral margins and central clearing resulting in increasing size of the lesions. The lesions are typically itchy and increase in number over a period of time. The affliction on legs and thighs is termed tinea corporis. It is occupational dermatoses in athletes and may be recurrent in them if due precautions are not taken.

Option A: Allergic contact dermatitis will present with itchy papulo-vesicular eruption at the site of contact of the allergen.

Option B: Fixed drug eruption presents with erythematous or hyperpigmented macules or patches, sometimes with central bullae. History of drug intake may be forthcoming and a history of recurrent such episodes at the same site may be present.

Option C: Psoriasis presents with papulosquamous lesions with micaceous scaling. Annular lesions may be present. Itching is not a feature.

Option D: Sarcoidosis may present with scaly plaques, however features of peripheral activity and central clearing are usually not seen and itching is not a feature.

[Q: 3677] OnExamination 2012 - Dermatology

A 20-year-old male presents with a very itchy rash afflicting both groins and suprapubic region of four weeks duration. On examination he had multiple annular scaly plaques with spreading peripheral borders and central clearing.

What is his diagnosis?

- 1- Allergic contact dermatitis
- 2- Dermatophytosis
- 3- Fixed drug eruption

- 4- Psoriasis
5- Sarcoidosis

Answer & Comments

Answer: 2- Dermatophytosis

Dermatophytosis is common in young active adults. It usually presents with annular scaly plaques with active peripheral margins and central clearing resulting in increasing size of the lesions. The lesions are typically itchy and increase in number over a period of time. The affliction of groins is referred to as 'tinea cruris' and involvement of limbs and trunk as 'tinea corporis'. Such patients can also be said to be suffering from 'tinea cruris et corporis'.

Option A: Allergic contact dermatitis will present with itchy papulo-vesicular eruption at the site of contact of the allergen

Option C: Fixed drug eruption present with erythematous or hyperpigmented macules or patches, sometimes with central bullae. History of drug intake may be forthcoming and history of recurrent such episodes at the same site may be present.

Option D: Psoriasis presents with papulosquamous lesions with micaceous scaling. Annular lesions may be present. Itching is not usually a prominent feature.

Option E: Sarcoidosis may present with scaly plaques, however features of peripheral activity and central clearing are usually not seen and itching is not a feature.

[Q: 3678] OnExamination 2012 - Dermatology

A 33-year-old female attends her GP concerned regarding a mole.

Which of the following characteristics of the lesion would raise suspicion that it is a malignant melanoma?

- 1- Lesion has irregular edge
2- Lesion is 5 mm in diameter

- 3- Lesion is pigmented uniformly
4- Lesion is present on face
5- Lesion is smoothly raised

Answer & Comments

Answer: 1- Lesion has irregular edge

The mnemonic of ABCDE regarding characteristics of a melanoma are as follows:

A - Asymmetry - one half of the lesion does not match the other half

B - Border irregularity

C - Colour variegation - pigmentation is not uniform

D - Diameter- a diameter 7 mm warrants investigation although changes in size are also important

E - Evolution - evolving size or changes in characteristics such as nodules.

[Q: 3679] OnExamination 2012 - Dermatology

Which of the following determines the primary mechanical properties of skin?

- 1- Dermis
2- Stratum basale

- 3- Stratum corneum
- 4- Stratum granulosum
- 5- Subcutaneous tissue

Answer & Comments

Answer: 3- Stratum corneum

The stratum corneum is the last layer and provides a mechanical barrier to the skin and therefore determines the mechanical functions of the skin. The hands and feet have thick stratum corneum as compared to the lips and eyelids. The thicker the stratum corneum is the more protection there is for the skin.

The dermis also has some factor to play with its elastic fibres and fibrous tissue.

The rest of the layers are also important but the mechanical properties are primarily determined by the stratum corneum.

[Q: 3680] OnExamination 2012 - Dermatology

A 25-year-old female presents with concerns regarding the unsightly appearance of her toe nails.

They have a whitish discolouration extending up the nail bed in a number of the toes of both feet. They are entirely painless and she is otherwise well.

What is the most appropriate treatment?

- 1- Oral fluconazole
- 2- Oral terbinafine
- 3- Topical benzoic acid
- 4- Topical fluconazole
- 5- Topical terbinafine

Answer & Comments

Answer: 2- Oral terbinafine

This young woman has typical features of fungal nail infection - onychomycosis - and the most appropriate treatment is oral antifungals

as topical antifungals may be effective for one or two nails but not where there are a number affected.

[Q: 3681] OnExamination 2012 - Dermatology

A 22-year-old female is referred with symmetrical, depigmented areas on the arms and legs but has been otherwise quite well.

Which one of the following diseases is most likely to be associated with her skin disease?

- 1- Diabetes mellitus
- 2- Hyperparathyroidism
- 3- Pernicious anaemia
- 4- Scleroderma
- 5- Systemic lupus erythematosus (SLE)

Answer & Comments

Answer: 3- Pernicious anaemia

This lady has vitiligo, which has a number of disease associations. It is the most common depigmenting disorder, and affects 0.5% of the world population. Half present before the age of 20, and there is no difference in rate between sexes, skin type or race. There seems to be a genetic basis to the disease, and familial clustering is seen.

The majority of diseases associated with vitiligo are autoimmune. Thyroid disease (particularly Hashimoto thyroiditis and Graves disease) is one of the strongest associations, and is often screened for in patients with vitiligo. HLA-B13 appears to be the link between thyroid disease and vitiligo.

9% of patients with pernicious anaemia have been shown to have vitiligo, compared to 5.7% with diabetes mellitus.

Other associations are Addison's disease, alopecia areata, rheumatoid arthritis, inflammatory bowel disease and psoriasis.

In addition, vitiligo may be a manifestation of polyglandular autoimmune syndrome, which includes HYPOparathyroidism rather than hyperparathyroidism.

SLE can cause a post-inflammatory hypopigmentation, but neither it or scleroderma have a recognised association with vitiligo.

[Q: 3682] OnExamination 2012 - Dermatology

A 17-year-old pregnant female attends antenatal clinic and is noted to have scattered small, raised lesions on her trunk and axillary freckles.

She was not aware of any of her family members having these lesions.

What is the likely mode of inheritance of this condition?

- 1- Autosomal dominant
- 2- Autosomal recessive
- 3- Trinucleotide repeating
- 4- X linked dominant
- 5- X linked recessive

Answer & Comments

Answer: 1- Autosomal dominant

This patient has neurofibromatosis with axillary freckling and neurofibromas.

This is usually inherited as autosomal dominant, although it may arise from a sporadic new mutation of the NF1 gene.

[Q: 3683] OnExamination 2012 - Dermatology

A 33-year-old female is admitted with erythema multiforme (EM) and erythematous lesions of the mouth and eyes.

Which one of the following drugs may account for her presentation?

- 1- Diazepam
- 2- Fluoxetine
- 3- Mebeverine
- 4- Oral contraceptive
- 5- Sulfasalazine

Answer & Comments

Answer: 5- Sulfasalazine

Any drug or infection can trigger EM but sulfasalazine and sulfa-group drugs are well reported as causes of EM and Stevens-Johnson syndrome.

[Q: 3684] OnExamination 2012 - Dermatology

A 36-year-old female presents with raised erythematous tender lesions on both legs which have developed since she had a throat infection two weeks ago.

Which one of the following investigations is most likely to establish the diagnosis?

- 1- Anti-streptolysin-O titre (ASOT)
- 2- Chest x ray
- 3- Mantoux test
- 4- Throat swab cultured for bacteria
- 5- Throat swab cultured for viruses

Answer & Comments

Answer: 1- Anti-streptolysin-O titre (ASOT)

This lady presents with tender lesions two weeks after a sore throat.

This is most likely to be post-streptococcal erythema nodosum and ASOT is most likely to confirm this.

[Q: 3685] OnExamination 2012 - Dermatology

Which of the following statements regarding psoriasis is most true?

- 1- Ciclosporin is ineffective in the treatment of psoriasis
- 2- Diagnosis requires histological confirmation
- 3- Guttate psoriasis often arises after staphylococcal infection
- 4- T cells play a prominent role in the pathogenesis of psoriasis
- 5- Twin studies have identified no genetic basis for psoriasis

Answer & Comments

Answer: 4- T cells play a prominent role in the pathogenesis of psoriasis

Diagnosis of psoriasis is based on clinical observation of sharply demarcated, erythematous, scaling plaques, and rarely requires biopsy.

Streptococcal infection is associated with precipitation and recurrence of guttate psoriasis.

Ciclosporin is a major inhibitor of T cell activation, and, given that T cells are central to the pathogenesis of psoriasis, is very effective treatment in psoriasis.

Genetic studies have led most experts to believe that psoriasis is the result of multiple genetic factors interacting with environmental stimuli. Genetic factors also seem to contribute to the clinical manifestations of the disease, for example, age of onset and severity of disease.

[Q: 3686] OnExamination 2012 - Dermatology

A 20-year-old male presents with extensive, coalescing, hypopigmented, slightly scaly lesions on his back and chest.

The rash had been present for two years and had gradually become more extensive. He had otherwise been in good health. The lesions were not symptomatic but he was concerned about their appearance.

What is the most appropriate treatment for his condition?

- 1- Aciclovir cream
- 2- Ketoconazole cream
- 3- Nystatin cream
- 4- Oral itraconazole
- 5- Oral terbinafine

Answer & Comments

Answer: 2- Ketoconazole cream

The patient presents with an asymptomatic eruption on his trunk. The lesions are scaly, hypopigmented and are not associated with any systemic disease. This is characteristic of pityriasis versicolor, which is caused by the unicellular yeast *Pityrosporum ovale* and *Pityrosporum orbiculare*. The yeast is lipophilic and is encouraged by an increase in environmental temperature, thus many patients notice that the condition begins after a summer vacation.

It is a disorder of the healthy, but the immunocompromised are at risk.

The condition is asymptomatic and appears pale in comparison to the normal skin. The fungus affects the melanocytes hence the hypo-pigmentation.

The treatment options include topical imidazole creams, selenium sulphide shampoo and, if not responding to topical treatment, oral itraconazole 200 mg once a day for seven days.

In this patient the topical treatment should be tried first.

[Q: 3687] OnExamination 2012 - Dermatology

A previously fit 30-year-old female presents with a four day history of intractable pruritus and urticaria.

What is the most appropriate initial management?

- 1- Chlorpheniramine
- 2- Prednisolone
- 3- Ranitidine
- 4- Topical hydrocortisone
- 5- Topical mepyramine

Answer & Comments

Answer: 1- Chlorpheniramine

Urticaria is a common condition and usually responds very well to systemic antihistamines which are the correct first line treatment.

Oral steroids can be given for severe cases but only as a last resort.

Topical steroids/topical antihistamines have no effect.

[Q: 3688] OnExamination 2012 - Dermatology

A 26-year-old man is noted to have cyanosis of the lower limbs and clubbing of the toes but not the fingers.

Which of the following statements is true?

- 1- He has coarctation of the aorta
- 2- He has Eisenmenger's syndrome
- 3- He has had a Blalock shunt operation
- 4- He is likely to have a loud continuous 'machinery' murmur below the left clavicle
- 5- He is likely to need urgent surgery

Answer & Comments

Answer: 2- He has Eisenmenger's syndrome

This is the differential cyanosis of a reversed patent ductus arteriosus (PDA). There is a right-left shunt from the pulmonary artery to the aorta just distal to the left subclavian artery.

Coarctation causes radiofemoral delay. It may be associated with PDA but there is no suggestion in this patient.

Continuous machinery murmur is the classic murmur of PDA but when the shunt reverses (as in patients with a large PDA and/or pulmonary disease) the murmur becomes softer and shorter.

When Eisenmenger's syndrome has developed surgery is associated with a very high mortality.

A Blalock shunt (anastomosis of subclavian artery to pulmonary artery) used to be performed for Fallot's tetralogy and leads to a weak left radial pulse.

[Q: 3689] OnExamination 2012 - Dermatology

A 40-year-old man presented with pityriasis versicolor.

What is the most appropriate treatment?

- 1- Methotrexate
- 2- Oral terbinafine
- 3- Phototherapy with ultraviolet light (UVB)
- 4- Psoralen with ultraviolet light (PUVA) therapy
- 5- Topical selenium sulphide

Answer & Comments

Answer: 5- Topical selenium sulphide

Pityriasis versicolor (also called tinea versicolor) is a skin lesion caused by a fungus called *Malassezia furfur*.

The treatment is topical selenium sulphide.

Oral itraconazole is also effective.

[Q: 3690] OnExamination 2012 - Dermatology

A 17-year-old girl presents with a two week history of urticaria.

Over the last couple of days she has been aware of new lesions occurring on a daily basis.

Which one of the following statements is most likely to be correct?

- 1- She is likely to have an associated asthma
- 2- She is likely to have taken penicillin recently
- 3- She is unlikely to have any identifiable trigger factor
- 4- The lesions will be present for at least 24 hours
- 5- There is likely to be a nut allergy

Answer & Comments

Answer: 3- She is unlikely to have any identifiable trigger factor

The commonest form of urticaria is idiopathic and there is no identifiable trigger.

Peanut allergy and penicillin may cause urticarial rashes but there is usually an associated specific history of contact with the allergen.

Urticarial lesions last less than 24 hours usually.

[Q: 3691] OnExamination 2012 - Dermatology

A 23-year-old female presents with a problem with her nails.

Over the last two months they have become rather unsightly and brittle. She has taken a selection of medications for acne.

Examination reveals onycholysis.

Which of the following preparations may be responsible for the onycholysis?

- 1- Dianette
- 2- Erythromycin
- 3- Isotretinoin
- 4- Tetracycline

- 5- Topical benzoic acid

Answer & Comments

Answer: 4- Tetracycline

Tetracycline is a recognised cause of onycholysis together with eczema, psoriasis and thyrotoxicosis to name but a few.

[Q: 3692] OnExamination 2012 - Dermatology

This 24-year-old woman presents with this rash for the past two weeks. She also complains of bilateral knee and ankle pains for the same duration of time.

What finding will be shown on a skin biopsy?

- 1- Fibrinoid necrosis and neutrophils within the walls of dermal capillaries
- 2- Intraepidermal clefting with eosinophils
- 3- Neutrophils within walls of medium sized arteries in the subcutis
- 4- Septal panniculitis
- 5- Subepidermal bulla with eosinophils

Answer & Comments

Answer: 1- Fibrinoid necrosis and neutrophils within the walls of dermal capillaries

The photograph reveals palpable purpura in a case of Henoch-Schönlein purpura (note the symptoms of arthralgia) on both legs. Leucocytoclastic vasculitis or Hypersensitivity angitis, histopathology reveals Fibrinoid degeneration, a neutrophilic infiltrate around small blood vessels along with karyorrhexis or nuclear dust arising out of disintegration of neutrophils.

Option B: This histological pattern is consistent with intraepidermal blistering conditions, for example, pemphigus.

Option C: This histological pattern is consistent with vasculitis affecting medium-

sized vessels, most commonly polyarteritis nodosa.

Option D: This histological pattern is consistent with erythema nodosum.

Option E: This histological pattern is consistent with subepidermal blistering disorders, for example, bullous pemphigoid.

[Q: 3693] OnExamination 2012 - Dermatology

A 35-year-old man has just been diagnosed with dermatitis herpetiformis.

Besides starting on a gluten-free diet, his dermatologist has decided to start him on oral dapsone.

What laboratory test needs to be within the normal range before commencing therapy?

- 1- Fasting glucose
- 2- Fasting lipids
- 3- Glucose-6-phosphate dehydrogenase (G6PD) levels
- 4- Haemoglobin-A1C levels (HbA1C)
- 5- Thiopurine methyltransferase (TPMT) levels

Answer & Comments

Answer: 3- Glucose-6-phosphate dehydrogenase (G6PD) levels

G6PD deficiency is an absolute contraindication to treatment with dapsone as it can lead to severe haemolytic anaemia. This is probably due to the N-hydroxy metabolites of dapsone, which are direct haemolytic agents. When allowed to build up to large enough amounts, they induce premature sequestration of the red cell in the spleen.

Options A, B and D: Abnormal HbA1C, fasting lipids and fasting glucose levels are not considered contraindications to treatment with dapsone.

Option E: TPMT levels are used to decide on starting doses of azathioprine.

[Q: 3694] OnExamination 2012 - Dermatology

This 6-month-old infant, who was born prematurely, presents with this lesion on his arm which was first noticed during the second week of life. It then progressively enlarged and deepened in colour over the next few months.

What is your most likely diagnosis?

- 1- Angiosarcoma
- 2- Lymphatic malformation
- 3- Haemangioma
- 4- Venous malformation
- 5- Kasabach-Merritt syndrome

Answer & Comments

Answer: 3- Haemangioma

Infantile haemangiomas are common vascular tumours that present in early infancy. They continue to enlarge and deepen in colour for the first few months of life before slowly involuting after six to 12 months. They are more common in premature infants.

Option A: Angiosarcomas, a high grade vascular malignancy, are very uncommon in infancy.

Option B: Lymphatic malformations are usually well formed at birth and do not have a proliferative stage like haemangiomas. They are usually skin coloured or bluish in appearance.

Option D: Venous malformations are usually well formed at birth and do not have a proliferative stage like haemangiomas. Clinically, they are usually skin coloured or have a bluish hue.

Option E: Kasabach-Merritt syndrome is seen in patients with kaposiform haemangioendothelioma, a rare vascular tumour seen in infants that present as a large,

firm, reddish-blue tumour. Patients usually have thrombocytopenia.

[Q: 3695] OnExamination 2012 - Dermatology

This 18-year-old man presents with this recurrent rash on both feet for the past two years. It worsened when football training started. He also has a history of allergic rhinitis.

What is your most likely diagnosis?

- 1- Bullous tinea pedis
- 2- Bullous pemphigoid
- 3- Erythema multiforme
- 4- Pompholyx / dyshidrotic eczema
- 5- Zoster

Answer & Comments

Answer: 4- Pompholyx / dyshidrotic eczema

Pompholyx or dyshidrotic eczema presents bilaterally on the hands and feet as itchy, erythematous blisters that resemble 'sago seeds'. It is commonly seen in young patients with a history of atopy and is more common in individuals who wear closed shoes or boots for long periods.

Option A: Bullous tinea pedis usually presents asymmetrically on one foot.

Option B: Bullous pemphigoid is very uncommon in this age group.

Option C: Erythema multiforme may present with acral blisters but are most commonly targetoid lesions. There is associated mucosal involvement.

Option E: Zoster presents as blisters in a dermatomal distribution, usually asymmetrically.

[Q: 3696] OnExamination 2012 - Dermatology

A young male presented with an itchy rash (above) on the buttocks and groins.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Atopic dermatitis
- 3- Dermatophytosis
- 4- Irritant contact dermatitis
- 5- Scabies

Answer & Comments

Answer: 3- Dermatophytosis

Dermatophytosis is caused by a fungal infection of the skin. It presents with itchy annular plaques with a clear centre and a spreading peripheral margin. It is termed tinea corporis when it affects the trunk or extremities and tinea cruris when it affects the natal cleft or groins.

Option A: Allergic contact dermatitis may present with an acute eczematous reaction at the site of contact with the allergen after a period of sensitisation.

Option B: Atopic dermatitis may present in the acute phase with an acute eczematous reaction on the face in infants. In adults the flexures are involved.

Option D: Irritant contact dermatitis presents with an acute eczematous reaction with erythema, vesiculation, crusting and itching or a burning sensation at the site of the contact of the irritant. A sensitisation dose is not required as in allergic contact dermatitis.

Option E: Scabies presents as itchy papular eruptions and burrows in the flexures including the web spaces.

[Q: 3697] OnExamination 2012 -
Dermatology

A young male patient presented with sharply circumscribed hyperpigmented skin lesions over the back.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Erythema multiforme
- 3- Fixed drug eruption
- 4- Folliculitis
- 5- Lichen planus

Answer & Comments

Answer: 3- Fixed drug eruption

Fixed drug eruption may present with sharply circumscribed pigmented macules, erythematous lesions or bullous lesions with a classical history of recurrence at the same site following the ingestion of the offending drug.

Option A: Allergic contact dermatitis is a form of contact dermatitis which follows contact with the offending agent such as chemicals, nickel and plants like poison ivy.

Option B: Erythema multiforme classically presents as discrete vesicular or bullous lesions surrounded by a pale area and a ring of erythema. However all three zones may not always be evident.

Option D: Folliculitis presents with painful papulopustular follicular lesions.

Option E: Lichen planus presents as violaceous polygonal papules usually around the ankles and wrists. Lichen planus pigmentosus may present in the dark skinned on the face and neck as dark to violaceous macules.

[Q: 3698] OnExamination 2012 -
Dermatology

A young otherwise healthy adolescent with multiple linear lacerations with the linear

lesions shown presented in various stages of healing with a vague history of possible antecedent causes.

What is the most likely primary diagnosis?

- 1- Contact dermatitis
- 2- Dermatitis artefacta
- 3- Hypertrophic scars
- 4- Keloids
- 5- Striae distensae

Answer & Comments

Answer: 2- Dermatitis artefacta

Option A: Contact dermatitis presents with itching, vesiculation or oozing in areas of contact with the offending allergen.

Option B (Correct answer): Dermatitis artefacta typically presents in a healthy individual with unexplained skin lesions which may be bizarre, sharply marginated geometric or linear tracks. Underlying psychiatric illness or a history of childhood neglect or abuse may be present.

Option C: Hypertrophic scars follow injuries and typically do not extend beyond the margins of the wound. As in keloids this case may present with multiple hypertrophic scars, however the primary diagnosis must be investigated.

Option D: Keloids may develop as sequelae to injuries where the overgrowth extends beyond the margins of the original injury with claw-like extensions. In this case such a patient may present with multiple keloids, however the primary diagnosis must be investigated.

Option E: Early striae may present as pinkish linear lesions of thinned skin and mature striae as white irregularly shaped bands of depressed areas of skin with their long axis parallel to lines of skin tension.

[Q: 3699] OnExamination 2012 -
Dermatology

A young adolescent girl presented with a rash in both axillary regions occurring a day after application of a new deodorant.

What is the most likely diagnosis?

- 1- Irritant contact dermatitis
- 2- Erythrasma
- 3- Herpes zoster
- 4- Intertrigo
- 5- Impetigo

Answer & Comments

Answer: 1- Irritant contact dermatitis

Option B: Erythrasma appears as reddish-brown slightly scaly patches with sharp borders. The patches occur in moist areas such as the groin, armpit, and skin folds. It is an infective condition caused by *Corynebacterium* spp.

Option C: Herpes zoster presents as grouped vesicular eruptions on an erythematous base in a dermatomal distribution.

Option D: Intertrigo is an inflammatory disorder of the skin affecting the folds commonly in the obese and diabetics and may become secondarily infected.

Option E: Impetigo commonly presents in children with painful bullous lesions with honey coloured crusts.

[Q: 3700] OnExamination 2012 -
Dermatology

A young adolescent male presented with multiple lesions on the face.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Comedones
- 3- Nodulocystic acne

- 4- Sycosis barbae
- 5- Tinea barbae

Answer & Comments

Answer: 2- Comedones

Option A: Allergic contact dermatitis will present with itchy papulo-vesicular eruption at the site of contact of the allergen.

Option C: Nodulocystic acne presents with multiple inflammatory lesions over the face.

Option D: Sycosis barbae presents clinically with inflammatory folliculocentric pustules.

Option E: Tinea barbae presents with itchy follicular lesions and annular plaques on glabrous areas of the face.

[Q: 3701] OnExamination 2012 -
Dermatology

A 15-year-old boy was treated with permethrin cream for scabies infestation.

On follow-up three weeks later he was found to have continuing infestation.

What is the most likely reason for this?

- 1- Facial skin was not treated
- 2- Non-disposal of underwear
- 3- Other household members were not treated
- 4- The organism is resistant to permethrin
- 5- The treatment was not repeated as prescribed

Answer & Comments

Answer: 3- Other household members were not treated

Scabies is an intensely pruritic and highly contagious infestation of the skin acquired through close personal contact.

A delayed type IV hypersensitivity reaction to the mites, their eggs, or excreta occurs

approximately 30 days after infestation and is responsible for the intense pruritus that is the hallmark of the disease.

All household members and close personal contacts should be treated whether or not they are symptomatic and patients should be re-examined two weeks after treatment to evaluate effectiveness.

Treatment failures are uncommon. Recurrence of the eruption usually means re-infection has occurred.

[Q: 3702] OnExamination 2012 - Dermatology

A young adolescent male presents with dystrophic nails, with debris on the under surface of the nails and elevated distal end of nail plate.

He also had scaly plaques on his elbows and knees.

What is the most likely diagnosis?

- 1- Alopecia areata associated nail dystrophy
- 2- Irritant contact dermatitis
- 3- Onychomycosis
- 4- Psoriasis
- 5- Trachyonychia

Answer & Comments

Answer: 4- Psoriasis

Option A: Alopecia areata produces fine nail pits in parallel rows in a 'tram track appearance'.

Option B: Chronic irritant dermatitis of the hands present with inflammation of the skin typically manifested by erythema, mild oedema, and scaling in the periungual region with nail plate discolouration affecting multiple fingers and thumbs.

Option C: Onychomycosis causes nail dystrophy resulting in the moth eaten

appearance. Tinea corporis usually causes annular scaly plaques which are itchy.

Option E: Trachyonychia or 20-nail-dystrophy may be seen in lichen planus or alopecia areata.

[Q: 3703] OnExamination 2012 - Dermatology

A 60-year-old male presents with a sudden onset eruption of blisters. He gives a history of pain in the affected area a day prior to the eruption of the blisters for which he applied a topical analgesic.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Folliculitis
- 3- Herpes zoster
- 4- Irritant contact dermatitis
- 5- Paederus dermatitis

Answer & Comments

Answer: 3- Herpes zoster

Option A: Allergic contact dermatitis presents with itchy papulo-vesicular eruption at the site of contact of the allergen.

Option B: Folliculitis presents with painful papulopustular follicular lesions.

Option D: Irritant contact dermatitis presents with vesicular eruption at sites of contact with the irritant, often on the exposed areas such as extremities. A burning sensation is experienced in irritant contact dermatitis as opposed to the itching in allergic contact dermatitis.

Option E: Paederus dermatitis is an acute irritant contact dermatitis which presents as plaques, linear streaks or 'kissing' lesions at sites where the offending pederin from the crushed beetle comes into contact with the skin.

[Q: 3704] OnExamination 2012 -
Dermatology

A mother brought her three children aged less than 10 years, all with the complaints of a rash around mouth and nose of 10 days duration.

The youngest child was affected first following which the other two children were affected. The lesions have been rapidly spreading in the affected area. Examination revealed 1-3 cms crusted erosions with golden yellow crusts around the lips and nares in all three children. The youngest child also had similar lesions on his hands.

What is the most likely diagnosis?

- 1- Ecthyma
- 2- Herpes simplex
- 3- Impetigo
- 4- Perioral dermatitis
- 5- Warts

Answer & Comments

Answer: 3- Impetigo

Option A: Ecthyma usually follows trivial trauma such as a scratch or insect bite on the legs and develops into a small pustular lesion on an erythematous base, with an adherent hard crust of dried exudate below which ulceration exists.

Option B: Herpes simplex infection presents with recurrent grouped vesicular eruptions on an erythematous base at mucocutaneous junctions.

Option D: Perioral dermatitis presents usually in women as vesicopustules around the mouth and rarely around the eyes, nose, or forehead. The rash appears very similar to acne.

Option E: Warts present with verrucous plaques and papules more commonly over extremities.

[Q: 3705] OnExamination 2012 -
Dermatology

A 40-year-old male presented with progressive discolouration of his great toe nail, which initially affected the distal part of the nail plate and progressively involved the more proximal parts of the same nail over a period of three months.

He also noticed a rash in the groins which had appeared approximately four weeks back.

Examination revealed a moth-eaten appearance of the right great toe nail with a scaly annular rash with an active peripheral margin in both groins.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Fixed drug eruption
- 3- Onychomycosis with tinea cruris
- 4- Psoriasis
- 5- Reiter's disease

Answer & Comments

Answer: 3- Onychomycosis with tinea cruris

Onychomycosis is not uncommon in males. It typically affects the distal part of the nail plate with progressive involvement of the proximal portions of the nail. The great toe may be the only affected nail, although it is not uncommon to find other toe nails also affected over a period of time.

The affliction of the great toe may be long standing and asymptomatic except for the disfigurement of the nail plate. The patient frequently consults the doctor when he or she develops other symptoms of dermatophytosis as a result of spread of the infection commonly by auto inoculation in areas such as the groins, trunk, extremities or the scalp.

Option A: Allergic contact dermatitis will present with itchy papulo-vesicular eruption at the site of contact of the allergen.

Option B: Fixed drug eruptions present with macules, erythematous or hyperpigmented or bullous lesions. History of drug intake may be forthcoming. Onset is sudden with rapid progression. Lesions are uncommonly scaly plaques which will not show typical peripheral activity of dermatophytosis.

Option D: Psoriasis presents with papulosquamous lesions with micaceous scaling. Annular lesions may be present. Itching is not a feature.

Option E: Reiter's disease typically presents with papulosquamous plaques, keratoderma blennorrhagica and circinate balanitis which are not itchy.

[Q: 3706] OnExamination 2012 - Dermatology

A father, 48-year-old, and his son, 20-year-old, presented with multiple itchy red lesions over their trunks and groins.

The son had developed the rash initially after working out in the local gym following which his father noticed a similar rash afflicting him.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Fixed drug eruption
- 3- Psoriasis
- 4- Sarcoidosis
- 5- Tinea corporis

Answer & Comments

Answer: 5- Tinea corporis

Dermatophytosis is common in young adults. It usually presents with annular scaly plaques with active peripheral margins and central clearing resulting in increasing size of the lesions. The lesions are typically itchy and increase in number over a period of time. The affliction of legs, thighs is termed tinea corporis. It is an occupational dermatoses in athletes and may be recurrent in them if due

precautions are not taken. The condition is contagious and can typically spread in immediate contacts such as family members if treatment is delayed or precautions are not taken.

Allergic contact dermatitis will present with itchy papulovesicular eruption at the site of contact of the allergen.

Fixed drug eruption presents with erythematous or hyperpigmented macules or patches, sometimes with central bullae. History of drug intake may be forthcoming and a history of other recurrent episodes at the same site may be present.

Psoriasis presents with papulosquamous lesions with micaceous scaling. Annular lesions may be present. Itching is not a feature.

Sarcoidosis may present with scaly plaques, however features of peripheral activity and central clearing are usually not seen and itching is not a feature.

[Q: 3707] OnExamination 2012 - Dermatology

A 38-year-old woman has erythematous plaques with hyperpigmentation at the edge and central hypopigmentation. Serological tests are unremarkable and the patient is diagnosed with discoid lupus.

Which of the following therapeutic strategies is most appropriate initially?

- 1- Cyclophosphamide
- 2- Dapsone
- 3- Methotrexate
- 4- Oral prednisolone
- 5- Sun protective measures

Answer & Comments

Answer: 5- Sun protective measures

Discoid lupus is photosensitive and so avoiding the sun with protective clothing and sunscreens, and changing behaviour is important.

Topical or intradermal steroids and hydroxychloroquine are useful therapies to prevent scarring and new lesions appearing. The latter are less effective if patients continue to smoke.

If these treatments are ineffective, second line drugs such as methotrexate, azathioprine, or thalidomide may be used.

[Q: 3708] OnExamination 2012 - Dermatology

A 51-year-old male presents with a rash that has been present intermittently over the last two years. On examination there is a symmetrical rash over the cheeks, nose and chin, with multiple papules and pustules.

What is the most appropriate therapy for this patient?

- 1- Flucloxacillin
- 2- Hydroxychloroquine
- 3- Isotretinoin
- 4- Oxytetracycline
- 5- Prednisolone

Answer & Comments

Answer: 4- Oxytetracycline

The description is that of acne rosacea particularly in view of the distribution, duration and absence of any other features. The most appropriate treatment is a tetracycline.

Isotretinoin although effective in rosacea is reserved for recalcitrant or fulminant cases.

Prednisolone is administered in rosacea fulminans.

[Q: 3709] OnExamination 2012 - Dermatology

Which of the following statements regarding psoriasis is correct?

- 1- 1% of patients have associated psoriatic arthropathy
- 2- Guttate psoriasis is the most common form of the disease
- 3- Psoriasis is more common at lower geographical altitudes
- 4- Psoriatic arthropathy precedes cutaneous lesions in roughly 20% of cases
- 5- The prevalence in the United Kingdom is 10%

Answer & Comments

Answer: 4- Psoriatic arthropathy precedes cutaneous lesions in roughly 20% of cases

The prevalence of psoriasis is reported as between 0.5 and 4.6%.

For reasons which may be explained by the filtering of ultraviolet B (UVB) light, psoriasis is more common at higher altitudes.

The commonest form of psoriasis is plaque psoriasis, making up approximately 80% of cases (guttate -10%, erythrodermic - 3%, pustular - 3%).

Studies report:

A 5-42% prevalence of psoriatic arthropathy in patients with cutaneous psoriasis and

Arthropathy precedes cutaneous lesions in 20%

Cutaneous lesions precede joint disease in 60-70% and

They occur simultaneously in 10-20%.

[Q: 3710] OnExamination 2012 -
Dermatology

A 65-year-old female who has a history of long-standing psoriasis and heavy alcohol intake, presents with a severe exacerbation of psoriasis. She was admitted and received topical therapy and over the month of her admission, her gamma-GT concentration had fallen from 400 U/L to 150 U/L (4-35).

Six weeks after discharge she was seen in outpatients where her psoriasis remained under control, but she complained of generalised hair loss.

What is the most likely cause for her hair loss?

- 1- Alopecia areata
- 2- Iron deficiency
- 3- Telogen effluvium
- 4- Thiamine deficiency
- 5- Trichotillomania

Answer & Comments

Answer: 3- Telogen effluvium

In a normal healthy person's scalp about 85% of the hair follicles are actively growing hair and 15% are resting.

If there is some shock to the system, as many as 70% of the scalp hairs can be precipitated into a resting state, thus reversing the usual ratio. Typical precipitants include illnesses, operations, accidents and childbirth.

The resting scalp hairs, now in the form of club hairs, remain firmly attached to the hair follicles at first. It is only about two months after the shock that the new hairs coming up through the scalp push out the 'dead' club hairs and increased hair fall is noticed. Thus, paradoxically, with this type of hair loss, hair fall is a sign of hair regrowth.

As the new hair first comes up through the scalp and pushes out the dead hair a fine fringe of new hair is often evident along the

forehead hairline. At first the fall of club hairs is profuse and a general thinning of the scalp hair may become evident but after several months a peak is reached and hair fall begins to lessen, gradually tapering back to normal over six to nine months.

As the hair fall tapers off the scalp thickens back up to normal, but recovery may be incomplete in some cases.

[Q: 3711] OnExamination 2012 -
Dermatology

A 38-year-old female presents with red target lesions confined to the hands and is diagnosed with erythema multiforme.

Which of the following could be the cause?

- 1- Cytomegalovirus infection
- 2- Group B streptococci
- 3- Langerhan's cells histiocytosis
- 4- Penicillin V
- 5- Ureaplasma urealyticum

Answer & Comments

Answer: 4- Penicillin V

Potential causes of erythema multiforme include:

1. Infections

Viruses: herpes simplex 1 and 2, hepatitis B, Epstein-Barr virus (EBV), enteroviruses

Small agents: Mycoplasma pneumoniae

Bacteria: Group A Streptococcus, eosin

Other: Mycobacterium tuberculosis, histoplasma, coccidioides.

2. Neoplasia

Leukaemia

Lymphoma.

3. Antibiotics

Penicillins, sulphonamides, isoniazid, tetracycline.

4. Anticonvulsants

Phenytoin, phenobarbitone, carbamazepine.

5. Other

Aspirin

Radiation therapy

Etoposide

NSAIDs

Sunlight

Pregnancy.

[Q: 3712] OnExamination 2012 - Dermatology

A 70-year-old woman complained of a rash that had developed over a month. She had otherwise been fit and well. On examination, there were numerous tense, fluid filled blisters over the trunk and limbs, but no mucosal involvement was evident.

What is the most likely diagnosis?

- 1- Dermatitis herpetiformis
- 2- Erythema multiforme
- 3- Herpes simplex
- 4- Pemphigoid
- 5- Pemphigus vulgaris

Answer & Comments

Answer: 4- Pemphigoid

The patient presents with tense blisters on her arms, trunk and legs. She is otherwise well and there is no mucosal involvement. This is typical of bullous pemphigoid.

Dermatitis herpetiformis presents with itchy excoriated areas in the elbows knees and buttocks.

Erythema multiforme presents with characteristic target lesions.

Herpes simplex is vesicular and in generalised cases the patient is likely to be unwell.

Pemphigus presents with superficial erosions and usually there is mucosal involvement.

[Q: 3713] OnExamination 2012 - Dermatology

A 30-year-old woman presents with a skin rash. On applying pressure to an unaffected area of skin it was relatively easy to induce trauma.

Increased fragility of the skin is characteristic of which of the following conditions?

- 1- Acute intermittent porphyria
- 2- Epidermolysis bullosa
- 3- Neurofibromatosis
- 4- Pseudo-xanthoma elasticum
- 5- Tuberous sclerosis

Answer & Comments

Answer: 2- Epidermolysis bullosa

Increased skin fragility is seen in a number of disorders and is used as a clinical test in bullous disorders (Nikolsky's sign).

Other causes include:

Pemphigus vulgaris

Porphyria cutanea tarda

Drug reactions (especially pseudoporphyria).

Other causes of increased skin fragility (not associated with bullae) include long term corticosteroid therapy, Ehlers-Danlos syndrome and scurvy (vitamin C deficiency).

[Q: 3714] OnExamination 2012 - Dermatology

An 18-year-old girl presents with this rash on both her upper arms and thighs for the past few years. It is generally asymptomatic.

Which of the following may be an associated skin condition?

- 1- Atopic dermatitis
- 2- Lichen planus
- 3- Nodulocystic acne
- 4- Pilonidal sinus
- 5- Psoriasis vulgaris

Answer & Comments

Answer: 1- Atopic dermatitis

This patient has keratosis pilaris, characterised by tiny, hyperkeratotic, follicular papules, most commonly affecting the upper arms and thighs. It is commonly seen in patients with atopic dermatitis.

Options B to E: There is no proven association with these other conditions.

[Q: 3715] OnExamination 2012 - Dermatology

A middle aged female patient presented with a non-itchy scaly rash on the scalp, elbows and knees.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Atopic dermatitis
- 3- Irritant contact dermatitis
- 4- Psoriasis
- 5- Tinea capitis

Answer & Comments

Answer: 4- Psoriasis

Option A: Allergic contact dermatitis may present with an acute eczematous reaction at

the site of contact with the allergen after a period of sensitisation.

Option B: Atopic dermatitis may present in the acute phase with an acute eczematous reaction on the face in infants. In adults the flexures are involved.

Option C: Irritant contact dermatitis presents as an acute eczematous reaction at the site of contact with the irritant.

Option E: Tinea capitis presents as itchy scaly plaques on the scalp along with loss of hair, presenting as 'black-dot' alopecia.

[Q: 3716] OnExamination 2012 - Dermatology

A young farmer presented with web space infection as shown.

What is the most likely causative organism?

- 1- Candida
- 2- Dermatophytes
- 3- Pseudomonas
- 4- Staphylococcus
- 5- Streptococcus

Answer & Comments

Answer: 3- Pseudomonas

Option A: Candidal web space infection presents as soft cottony growth in the macerated web space.

Option B: Dermatophyte infection of the web space results in an itchy scaly lesion usually with affliction of the forefoot or the dorsum with an annular scaly plaque of tinea pedis.

Option D: Staphylococcus and Option E: Streptococcus infections present with painful blistering maceration of the affected web space.

Pseudomonas intertrigo typically presents with a bluish to greenish pigmentation in the affected areas. In the typical 'immersion foot'

the affected area is sodden and macerated with inhibition of the Gram positive bacteria and dermatophytes. Secondary invasion after pseudomonal infection is possible with Candida.

[Q: 3717] OnExamination 2012 - Dermatology

A 30-year-old female presented with mildly itchy violaceous papular eruptions on the dorsum of feet, ankles, wrist and low back.

What is the most likely diagnosis?

- 1- Lichen planus
- 2- Papular urticaria
- 3- Pityriasis rosea
- 4- Psoriasis
- 5- Scabies

Answer & Comments

Answer: 1- Lichen planus

Option B: Papular urticaria presents as chronic or recurrent erythematous papules caused by a hypersensitivity reaction to insect bites.

Option C: Pityriasis rosea presents as annular papulosquamous plaques with a peripheral collarette of scales.

Option D: Psoriasis presents as papulosquamous plaques over the extensors with micaceous scaling.

Option E: Scabies presents with itchy papules and burrows in flexors and web spaces of the hands and feet.

[Q: 3718] OnExamination 2012 - Dermatology

A young female patient presented with the above rash of few hours duration after tending her garden. She had a similar milder rash on the arms a few weeks ago.

What is the most likely diagnosis?

- 1- Allergic contact dermatitis
- 2- Folliculitis
- 3- Herpes zoster
- 4- Irritant contact dermatitis
- 5- Paederus dermatitis

Answer & Comments

Answer: 1- Allergic contact dermatitis

Folliculitis presents with painful papulopustular follicular lesions.

Herpes zoster presents with acute onset grouped vesicular eruptions in dermatomal distribution.

Irritant contact dermatitis presents with vesicular eruption at sites of contact with the irritant, often on the exposed areas such as extremities.

Paederus dermatitis is an acute irritant contact dermatitis which presents as plaques, linear streaks or 'kissing' lesions at sites where the offending pederin from the crushed beetle comes into contact with the skin.

The question mentions a past history of similar complaints a few days back. Allergic contact dermatitis needs a sensitization dose following which the subsequent exposures manifest early with severe manifestations. Irritant contact dermatitis does not need a sensitization dose and manifests almost immediately after exposure.

This case had a milder sensitization exposure earlier followed by a severe reaction on the subsequent exposure. Hence it is a case of Allergic contact dermatitis.

[Q: 3719] OnExamination 2012 - Dermatology

A 50-year-old male presented with bullous lesions on both his feet. He also had dystrophic nails and an itchy scaly rash

affecting the groins and interdigital web spaces of his feet.

What is the most likely diagnosis?

- 1- Bullous impetigo
- 2- Bullous pemphigoid
- 3- Bullous tinea pedis
- 4- Erythema multiforme
- 5- Herpes zoster

Answer & Comments

Answer: 3- Bullous tinea pedis

Option A: Bullous impetigo presents with painful bullous lesions in children.

Option B: Bullous pemphigoid commonly starts with itching and a non-specific rash on the limbs that may be either urticaria-like or occasionally eczematous. It presents as erythematous and urticated plaques followed by tense blisters over the affected areas of trunk, limbs and flexures.

Option D: Erythema multiforme classically presents with target lesions with a central bullous lesion surrounded by an erythematous halo following the intake of an offending drug.

Option E: Herpes zoster presents with vesicobullous lesions in a dermatomal distribution.

[Q: 3720] OnExamination 2012 - Dermatology

A 12-year-old child presents with the above depressed sclerotic linear lesion of two years duration with a history of initial progression and thereafter a static phase.

What is his diagnosis?

- 1- Acrodermatitis chronica atrophicans
- 2- Aplasia cutis
- 3- En coup de sabre
- 4- Post traumatic scar

- 5- Scleroedema

Answer & Comments

Answer: 3- En coup de sabre

En coup de sabre, a variant of scleroedema is characterised by a linear, atrophic depression affecting the frontoparietal aspect of the face and scalp, suggestive of a stroke from a sword, as shown in the image. Such lesions may extend into the underlying tissues. Scalp involvement results in scarring alopecia.

Option A: Acrodermatitis chronica atrophicans affects the acral parts and not the scalp.

Option B: Aplasia cutis is congenital absence of skin. It is present at birth.

Option D: Post traumatic scar will present with obvious history of trauma in such a case. Scarring will be evident while this child has sclerosis with no obvious scarring.

Option E: Scleroedema is a misnomer. It presents with induration and occasional erythema. The lesions reveal no sclerosis and although it can present over the face, linear lesions such as this are absent.

[Q: 3721] OnExamination 2012 - Dermatology

A young male athlete presented with pedal hyperhidrosis with a non-itchy rash on both soles, with foul odour.

Examination revealed well sculpted painless pits of varying depths along both soles symmetrically.

What is the most likely diagnosis?

- 1- Corns
- 2- Erythrasma
- 3- Pitted keratolysis
- 4- Plantar warts
- 5- Tinea pedis

Answer & Comments

Answer: 3- Pitted keratolysis

Pitted keratolysis is a common infection of the thickly keratinised areas of the plantar soles by *Micrococcus sedentarius*.

It presents with sharply defined pits in the thick skin of the plantar surface of feet in areas which stay in contact with footwear in young adults. It is usually associated with pedal hyperhidrosis which promotes maceration and hence facilitates bacterial penetration. The lesions are usually non-tender.

Plantar warts are usually painful, however they may present as a mosaic collection which may be non-tender and tinea pedis presents with itchy plaques classically over the instep of the soles in an asymmetric fashion.

Option A: Corns are painful keratotic lesions which develop at pressure points.

Option B: Erythrasma appears as reddish-brown slightly scaly patches with sharp borders. The patches occur in moist areas such as the groin, armpit, and skin folds.

Option D: Plantar warts present with solitary or multiple painful verrucous lesions on the soles with obvious loss of skin markings over the lesions.

Option E: Tinea pedis presents with itchy scaly plaques typically over instep of soles and between toes.

[Q: 3722] OnExamination 2012 - Dermatology

A 43-year-old female presents with a weepy, erythematous rash mainly affecting the forehead, scalp, neck and upper back.

Three days earlier she had used red hair dye at home to self-administer 'highlights'.

What is the likely diagnosis?

1- Acne rosacea

2- Contact allergic dermatitis

3- Lupus erythematosus

4- Psoriasis

5- Seborrhoeic dermatitis

Answer & Comments

Answer: 2- Contact allergic dermatitis

Hair dye contains substances which may induce an eczematous response in form of contact allergic dermatitis.

This type of reaction is typical for this sort of time scale, and is an example of a type IV, or delayed, hypersensitivity reaction.

Sensitisation occurs on initial exposure to the allergen and 'memory' T-cells proliferate in lymphoid tissue. Subsequent exposure to allergen induces activation of the T-lymphocytes and an inflammatory response.

Hairdressing chemicals are a very common cause of contact allergic dermatitis, a disorder which is very common amongst the hairdressing community.

A lady at this age is unlikely to present with a new, previously undiagnosed case of eczema.

Acne rosacea is usually a disorder of the skin on the cheeks and nose.

Acute cutaneous lupus erythematosus presents with an erythematous rash over the face and neck. However there are no eczematous features.

[Q: 3723] OnExamination 2012 - Dermatology

A 40-year-old female presents with a six month history of pruritic papules, vesicles and excoriations on the elbows, knees, buttocks and scalp.

Her GP has prescribed topical betamethasone therapy which has been unhelpful.

What is the most likely diagnosis?

- 1- Atopic dermatitis (eczema)
- 2- Dermatitis herpetiformis (DH)
- 3- Henoch-Schönlein purpura (HSP)
- 4- Psoriasis
- 5- Scabies

Answer & Comments

Answer: 2- Dermatitis herpetiformis (DH)

The question describes the characteristic distribution of the lesions of dermatitis herpetiformis.

DH is one of the immunobullous conditions and characteristically has very intensely pruritic vesicles. It is not usually responsive to topical steroids, but would respond well to dapsone. It is associated with gluten sensitivity and coeliac disease.

Atopic eczema is non-vesicular and would respond to potent topical steroids.

HSP is a purpuric rash and is non-pruritic.

Scabies usually affect the extremities and rarely affect above the neck line. They do not cause papules and vesicles.

[Q: 3724] OnExamination 2012 - Dermatology

During a follow up visit at an asthma clinic a 38-year-old female complains of the appearance of a mole.

Which of the following characteristics of the lesion would raise suspicion that it is a malignant melanoma?

- 1- Lesion has irregular outline
- 2- Lesion is deeply pigmented
- 3- Lesion is present on face
- 4- Lesion is raised
- 5- Lesion is 6 mm in diameter

Answer & Comments

Answer: 1- Lesion has irregular outline

The mnemonic of ABCDE regarding characteristics of a melanoma are as follows:

A - Asymmetry - one half of the lesion does not match the other half

B - Border irregularity

C - Colour variegation - pigmentation is not uniform

D - Diameter- a diameter 7 mm warrants investigation although changes in size are also important

E - Evolution - evolving size or changes in characteristics such as nodules.

[Q: 3725] OnExamination 2012 - Dermatology

A 40-year-old female presents with a long history of excessive localised armpit sweating.

She finds the problem embarrassing and has problems staining clothes. She has tried antiperspirants without relief.

Which is the most appropriate treatment that you would offer this patient?

- 1- Amitriptyline
- 2- Axillary surgery
- 3- Botulinum toxin injection
- 4- Propantheline
- 5- Topical aluminium salts

Answer & Comments

Answer: 3- Botulinum toxin injection

This woman has primary hyperhidrosis which can be quite psychologically disabling.

In this case the most appropriate treatment would be botulinum toxin injection to each axilla. This treatment is licensed for use and would be the preferred treatment before

aluminium salts, as antiperspirants have failed.

Similarly, antimuscarinics are associated with systemic side effects that may prove intolerable and their efficacy is really not proven.

Pharmacological approaches should be tried before surgery.

[Q: 3726] OnExamination 2012 - Dermatology

A 20-year-old female with a history of systemic lupus erythematosus presents with symmetrical reticulated, violaceous patches, which become more prominent in cold weather involving both lower limbs.

Which of the following is the likely diagnosis?

- 1- Erythema ab igne
- 2- Erythema marginatum
- 3- Erythema nodosum
- 4- Livedo reticularis
- 5- Pyoderma gangrenosum

Answer & Comments

Answer: 4- Livedo reticularis

Livedo reticularis is due to dilation of capillary blood vessels and stagnation of blood within these vessels producing a mottled discolouration of the skin.

It is described as being reticular (net-like) cyanotic cutaneous discolouration surrounding pale central areas. It occurs mostly on the legs, arms and trunk and is more pronounced in cold weather.

Mostly it is idiopathic, or secondary to

Malignancy

Vasculitis

SLE

Cancer and

Cholesterol embolisation.

[Q: 3727] OnExamination 2012 - Dermatology

A 72-year-old woman presents with a longstanding leg ulcer.

Which of the following minerals is most important in wound healing?

- 1- Copper
- 2- Magnesium
- 3- Potassium
- 4- Selenium
- 5- Zinc

Answer & Comments

Answer: 5- Zinc

Certain supplements are important in wound healing particularly zinc, vitamin C and arginine.

Zinc is a component of many of the enzymes responsible for wound healing.

[Q: 3728] OnExamination 2012 - Dermatology

A 52-year-old female presents with blistering of the hands and arms which deteriorates during the summer. She is otherwise well and drinks approximately 20 units of alcohol weekly.

Examination of her skin revealed erosions and scarring on the backs of her hands and forearms, and some mild hirsutism.

Which one of the following is the most likely diagnosis?

- 1- Acute intermittent porphyria
- 2- Erythropoietic protoporphyria
- 3- Pemphigoid
- 4- Porphyria cutanea tarda (PCT)
- 5- Subacute lupus erythematosus (LE)

Answer & Comments

Answer: 4- Porphyria cutanea tarda (PCT)

The history of photosensitive eruption, hypertrichosis and milia formation (keratin-containing cysts) are characteristic of PCT.

Acute intermittent porphyria usually causes intermittent neurological and abdominal problems.

Subacute LE can cause erythema and scarring, but in a patient with increased alcohol intake and hypertrichosis the most likely diagnosis is PCT.

Erythropoietic protoporphyria patients get pain and erythema on exposure to sunlight.

[Q: 3729] OnExamination 2012 - Dermatology

A 16-year-old girl is seen in clinic as she is concerned due to areas of hair loss on the scalp.

Past medical history includes atopic eczema and she has a number of depigmented areas on her hands.

What is the most likely diagnosis?

- 1- Alopecia areata
- 2- Hypothyroidism
- 3- Seborrhoeic dermatitis
- 4- Systemic lupus erythematosus
- 5- Trichotillomania

Answer & Comments

Answer: 1- Alopecia areata

This girl has a combination of vitiligo and alopecia areata which can co-exist and have similar autoimmune aetiology.

Discrete areas of hair loss and normal texture on the scalp are highly suggestive of alopecia areata.

[Q: 3730] OnExamination 2012 - Dermatology

In the treatment of psoriasis, which of the following statements is correct?

- 1- Etanercept is not effective in psoriatic arthritis
- 2- Infliximab is associated with tuberculosis
- 3- PUVA is ineffective
- 4- Retinoids are the most useful monotherapy in psoriatic patients
- 5- Vitamin D analogues are associated with cutaneous atrophy

Answer & Comments

Answer: 2- Infliximab is associated with tuberculosis

Psoralen and ultraviolet light (PUVA) is an effective treatment for psoriasis but has been related to increased risk of squamous cell carcinoma, and possibly malignant melanoma.

Retinoids are most effective in combination therapy especially with ultraviolet B (UVB) phototherapy and PUVA.

Part of the attraction of vitamin D analogues over steroids is that they do not cause cutaneous atrophy whereas steroids do.

The recombinant tumour necrosis factor and receptor fusion protein, etanercept, has demonstrated considerable beneficial effects on psoriatic arthropathy in placebo controlled, double blind studies.

Infliximab is associated with tuberculosis by reactivation of latent disease. Thus it is advised that patients who are to be treated with infliximab are tuberculin tested and if required receive chest radiography.

[Q: 3731] OnExamination 2012 -
Dermatology

A 58-year-old man has a history of obesity, gastro-oesophageal reflux disease, low back pain and IHD.

He presents with large, itchy weals over the trunk and limbs and a sensation of tightness in the throat.

Which one of the following drugs is the most likely to have triggered this skin eruption?

- 1- Aspirin
- 2- GTN (nitrate) spray
- 3- Omeprazole
- 4- Paracetamol
- 5- Simvastatin

Answer & Comments

Answer: 1- Aspirin

In hypersensitive patients, aspirin can cause:

Angioedema
Bronchospasm
Urticaria (skin rashes).

[Q: 3732] OnExamination 2012 -
Dermatology

Which is true regarding eczema herpeticum?

- 1- Is invariably fatal if untreated
- 2- Is more severe in reactivation disease
- 3- Is typically associated with a high fever for over a week
- 4- Only a single crop of vesicles usually appear
- 5- Usually has an indolent onset

Answer & Comments

Answer: 3- Is typically associated with a high fever for over a week

Eczema herpeticum is the result of primary infection of eczematous skin with Herpes

simplex virus (HSV). The severity varies from mild to fatal.

There is usually an abrupt onset with crops appearing over seven to nine days. These may become coalesced. Typically, the child has a high fever for seven days, and recurrent attacks can occur.

Death can result from physiological disturbances (loss of fluid electrolytes and protein through the skin) or dissemination of the virus to brain and other organs or from secondary bacterial sepsis.

[Q: 3733] OnExamination 2012 -
Dermatology

What is the most common presenting feature of porphyria cutanea tarda?

- 1- Acute blistering crises affecting the trunk and limbs
- 2- Acute redness and swelling following sun exposure
- 3- Erythroderma
- 4- Generalised hypertrichosis
- 5- Skin fragility and blistering affecting the hands, face and scalp

Answer & Comments

Answer: 5- Skin fragility and blistering affecting the hands, face and scalp

Porphyria cutanea tarda (PCT) is a term that encompasses a group of related disorders, all of which arise from deficient activity of the haeme-synthetic enzyme uroporphyrinogen decarboxylase (URO-D) in the liver.

The porphyrins produced in PCT are photoactive molecules that absorb light energy strongly in the visible violet spectrum. Photoexcited porphyrins in the skin mediate oxidative damage to biomolecular targets, causing cutaneous photosensitivity reactions.

The most common presenting sign of PCT is fragility of sunexposed skin after mechanical trauma, leading to erosions and bullae, worst on dorsal hands, forearms and face.

[Q: 3734] OnExamination 2012 - Dermatology

A 75-year-old female presents with chronic leg ulceration which is a consequence of venous insufficiency.

Which one of the following is the most appropriate management?

- 1- Appropriate systemic antibiotic in preparation for skin grafting
- 2- Compression bandaging
- 3- Improve the venous return by limb elevation
- 4- Skin biopsy to exclude neoplasm
- 5- Vein surgery exclusion of neoplasm by skin biopsy

Answer & Comments

Answer: 2- Compression bandaging

Venous ulcers are secondary to venous stasis and chronic stretching vessel of the vein walls of the superficial veins.

These eventually become thinner and ulcerate.

The only treatment shown in studies to be beneficial for this condition would be to compress the superficial venous using a four layer compression bandage.

The patient should always have their Doppler's and ABPI (ankle brachial pulse index) prior to compression. This should be greater than 1.

[Q: 3735] OnExamination 2012 -
Ethics and law

An 85-year-old lady with advanced Alzheimer's dementia has inhaled her hearing aid. The respiratory rate is 35. A bronchoscopy is proposed.

Which of the following apply with regard to obtaining consent for the procedure?

- 1- If the mini mental score is above 20/30, consent can be taken from patient
- 2- Psychogeriatric opinion is needed before consent can be obtained
- 3- Relatives/next of kin will have to consent for the patient
- 4- The doctor will be able to consent for the patient
- 5- The procedure does not require a written consent

Answer & Comments

Answer: 5- The procedure does not require a written consent

In this case, which is an emergency, informed written consent is not essential as the procedure is potentially life-saving and the doctor would be seen to be acting in the patient's best interest.

The process of consent for a procedure relies upon written and informed consent which the patient has to understand.

When a patient has impaired mental capacity, the doctor may be uncertain whether the patient is competent to give informed consent. Under English law no other person can consent to treatment on behalf of an adult, though it is desirable that next of kin are consulted before treating an adult without consent.

Recent legislation gives legal authority to people appointed by the patient, or by the state, or a relative or carer, to consent (or refuse) on behalf of the patient.

A mini-mental score may not adequately identify those unable to give consent.

[Q: 3736] OnExamination 2012 -
Ethics and law

A patient of yours suffers a myocardial infarction and dies in Spain. His relatives arrange for his body to be repatriated and plan for him to be cremated.

You last saw him alive seven days before his death.

Which of the following is true with respect to completion of cremation forms?

- 1- A colleague should complete form 4
- 2- A cremation may only take place if a coroner rules that no inquest or post mortem is needed
- 3- The Spanish doctor who originally treated him should complete form 4
- 4- You are allowed to complete form 5
- 5- You are allowed to complete forms 4 and 5

Answer & Comments

Answer: 2- A cremation may only take place if a coroner rules that no inquest or post mortem is needed

Where deaths abroad are concerned, a cremation may only take place if the coroner is satisfied that a post mortem or inquest is not necessary.

It is highly unlikely that you will be in a position to complete forms 4 and 5, and it is not appropriate for form 4 to be completed by the Spanish doctor who originally treated the patient.

Ministry of Justice cremation guidelines

[Q: 3737] OnExamination 2012 -
Ethics and law

You are the general practitioner of a 76-year-old man who has been suffering from

bronchial carcinoma for the past one and a half years. He is requiring increasing amounts of morphine to cope with his pain, and he dies in his sleep.

You certify the cause of death as bronchial carcinoma.

His wife who requests cremation asks to see form 4.

Which of the following is true with respect to her viewing the form?

- 1- She is not allowed to view it in any circumstances
- 2- The form should be typewritten if possible
- 3- The name of the completing doctor must be obscured
- 4- You can apply for certain information not to be disclosed by discussing this with the referee
- 5- You cannot prevent her from reviewing all aspects of the form

Answer & Comments

Answer: 4- You can apply for certain information not to be disclosed by discussing this with the referee

The recent cremation regulations detail that the cremation applicant can view the form.

There may be circumstances though when you wish for certain information not to be disclosed, that the patient may have told you in confidence. In this case you can write to the cremation referee requesting that certain pieces of information are withheld.

In the case of a patient with an underlying carcinoma this might be details around the diagnosis or co-morbidities that the patient may have withheld from relatives during life.

When you complete the form it is important that you remember the information may be seen by a relative; also make sure that your handwriting is as legible as possible.

Ministry of Justice cremation guidelines

[Q: 3738] OnExamination 2012 - Ethics and law

A 30-year-old male is unconscious on admission following a road traffic accident. He was the driver of the car and there is the suspicion that he was responsible for the accident in which a passenger of another car died. In attendance with the patient is his wife who was uninjured in the accident. The police are keen to obtain a blood sample for alcohol measurement but the patient is incapable of giving consent for this procedure.

What is the most appropriate action in these circumstances?

- 1- Inform the police that you may only take blood samples on medical grounds.
- 2- Draw a blood sample for later analysis when the patient is competent to consent.
- 3- Draw a blood sample which can be analysed immediately.
- 4- Obtain consent from his wife, as next of kin, to draw the blood sample.
- 5- Refuse to obtain a blood sample until the patient is competent to provide consent.

Answer & Comments

Answer: 2- Draw a blood sample for later analysis when the patient is competent to consent.

There is clear guidance published on such a situation by the BMA. Following the Police Reform Act, it is no longer necessary to obtain consent from unconscious or incapacitated drivers. However, the sample is not tested until the person regains competence and gives valid consent to it being tested. A competent person who refuses to allow his or her sample to be tested might be liable to prosecution. Similarly, the new law recognises the duty to justice.

[Q: 3739] OnExamination 2012 -
Ethics and law

You intend to undertake a study of patients who have undergone excision of minor lumps and bumps over the last five years.

Specifically you wish to compare post-operative infection rates and also whether there are any differences between the clinical diagnosis and the histological diagnosis between the differing grades of practitioner performing the procedure.

Which of the following statements are correct concerning this study?

- 1- Approval for the study must be obtained from the local ethics committee.
- 2- If a study has already published with exactly the same concept then this constitutes plagiarism.
- 3- If such a study has already been published then the investigators must obtain consent from the original authors to replicate their work.
- 4- The study is flawed in its design and should not be performed.
- 5- This is an audit and does not require ethical committee approval.

Answer & Comments

Answer: 1- Approval for the study must be obtained from the local ethics committee.

This is not an audit.

There is no information provided to indicate that there are either any local or national guidelines relating to such a study. Furthermore, there is no information provided to indicate that there is a specific clinical problem to which an audit should be addressed.

Consequently, this is a research study and is a retrospective study. As such, it requires local ethical committee approval.

The study itself seems very reasonable and even if it were published elsewhere it would still be reasonable to perform in the investigator's practice as the outcomes may be completely different.

Using the same methods as another study is perfectly justifiable, if only to prove the veracity of the original publication.

No consent is required from the original authors if a similar study has already been published.

[Q: 3740] OnExamination 2012 -
Ethics and law

You are intending to publish a case report as a fascinoma of the month within a national medical journal. As part of the publication you provide an image from the MRI film of the abdomen.

Medical Illustration have transferred the film to electronic format and have removed all patient identification markings. The case report itself is otherwise completely anonymous.

Which of the following concerning consent is correct?

- 1- Consent for publication may not be required depending on the journal to which the manuscript is submitted
- 2- Consent for publication must be sought from the local ethics committee
- 3- Consent for publication of the image must be obtained from the radiologist
- 4- Patient consent for publication is not required
- 5- Patient consent must be provided for publication

Answer & Comments

Answer: 5- Patient consent must be provided for publication

There is much controversy concerning case reports and consent but without question, prior to publication, and particularly as you are using images, consent for publication must be obtained from the patient for use of both images and for the publication of the case report.

This consent must also be appropriately informed.

All UK journals expect this prior to publication despite the anonymity of the subject matter.

This is not an issue for which medical ethics committees are involved.

This is a complex area and there is flexibility around publication of images. However, there have been incidences of x rays being published which have been deemed to have been an invasion of privacy.

[Q: 3741] OnExamination 2012 - Ethics and law

Does integrity refer to a virtue that requires the physician to do the following?

- 1- Acknowledge and respond to the suffering of patients
- 2- Ignore irrelevant differences between the physician and the patient
- 3- Practise medicine according to intellectual and moral standards of excellence
- 4- Risk health and life in the care of patients
- 5- Treat in the best interests of the patient

Answer & Comments

Answer: 3- Practise medicine according to intellectual and moral standards of excellence

Integrity refers to the practise of medicine according to appropriate ethical standards and excellence.

[Q: 3742] OnExamination 2012 - Ethics and law

By which of the following are most deaths determined?

- 1- Absent pulse
- 2- Brain stem tests
- 3- Loss of pupillary reflex
- 4- The absence of vital signs
- 5- The coroner

Answer & Comments

Answer: 4- The absence of vital signs

The absence of vital signs is the commonest mode of diagnosing death and entails

Absent pulse

Absent heart sounds

Respiratory arrest and

Loss of pupillary light reflex.

Brain stem tests are generally reserved for ventilated cases where organ transplantation may be required.

Doctors most commonly diagnose death not the coroner who provides a verdict on the cause of death.

[Q: 3743] OnExamination 2012 - Ethics and law

A placebo is defined as which of the following?

- 1- A standard treatment against which a newer treatment is compared
- 2- A substance given as a treatment for a disorder
- 3- A way to deceive a patient into taking a medication
- 4- An inert substance given as a medicine in an assessment of its suggestive effect

- 5- The medication given to a patient for a specific type of ailment

Answer & Comments

Answer: 4- An inert substance given as a medicine in an assessment of its suggestive effect

A placebo typically produces mainly a psychological effect when administered to a patient or person involved in a trial.

[Q: 3744] OnExamination 2012 - Ethics and law

Which medical procedure highlighted the need for new methods of defining and determining death in the face of continued cardiorespiratory function?

- 1- Artificial resuscitation
- 2- Brain surgery
- 3- ITU ventilation
- 4- Open heart surgery
- 5- Organ transplantation

Answer & Comments

Answer: 5- Organ transplantation

The conventional criteria previously established for clinical death were based upon lack of cardiorespiratory function.

The development of organ transplantation highlighted patients who had conditions incompatible with life, but who continued to have some form of cardiorespiratory function with artificial support. This led to a code of practice for the diagnosis of brainstem death.

This is based on the knowledge that when the brainstem is damaged to such a degree that its functions are irreversibly destroyed, the heart will inevitably stop beating shortly afterwards. When this occurs, therefore, the patient is dead even though respiration and circulation can be artificially maintained.

Brain stem function is checked through set criteria, and the findings must be agreed by at least two senior doctors. 'Life-support' should be withdrawn at this point, but consideration should be taken as to whether the person would be a suitable organ donor.

[Q: 3745] OnExamination 2012 - Ethics and law

A 76-year-old female was admitted 24 hours ago following a fall.

The orthopaedic senior house officer asks for your help because the patient is shouting out on the ward keeping all the other patients in the bay awake. He tells you that he is not able to reason with her and that she is distracted and incoherent. On arrival you note that her left leg is shortened and externally rotated.

Which one of the following additional findings would suggest a diagnosis of delirium rather than dementia?

- 1- A positive Urine dipstick
- 2- MMSE of 28 in the patient's notes that was done six months ago
- 3- The patient has been given lorazepam with minimal effect
- 4- The patient is febrile at 38?
- 5- The patient was coherent and compliant on admission

Answer & Comments

Answer: 5- The patient was coherent and compliant on admission

Delirium is diagnosed using the DSM-IV classification or short confusion assessment method (CAM).

Features of CAM are:

Acute onset and fluctuation course (within the last day)

Inattention

Disorganised thinking

Altered level of consciousness (hypo- or hyperactive).

For a diagnosis of delirium the patient must have 1 and 2 and either 3 or 4.

Answer A is incorrect because a positive dipstick may help you to ascertain a cause for delirium, but you have to use CAM for the diagnosis.

Answer B is incorrect because a MMSE of 28 done six months ago shows you that the patient was cognitive intact six months ago, but you have to use CAM to diagnose delirium.

Answer C is incorrect because you have to use CAM to diagnose delirium.

Answer D is incorrect because a fever may help you to ascertain the cause for delirium, but you have to use CAM for the diagnosis.

[Q: 3746] OnExamination 2012 - Ethics and law

A 63-year-old smoker has been investigated for a cough and chest pain and a diagnosis of bronchial carcinoma is made on a plain chest x ray examination.

Before a tissue diagnosis can be made, he dies in hospital of a large and unexpected haemoptysis and a post mortem examination is carried out with the consent of the relatives. At this examination, the correct diagnosis is shown to be tuberculosis and there is no carcinoma.

In this circumstances, is it mandatory to make a report to a particular authority, and if so, which?

- 1- Consultant in Communicable Diseases Control
- 2- Coroner
- 3- General Medical Council
- 4- Health and Safety Executive
- 5- Strategic Health Authority

Answer & Comments

Answer: 1- Consultant in Communicable Diseases Control

A diagnosis of bronchial carcinoma cannot be made without a tissue biopsy.

There are a number of notifiable infectious diseases that it is mandatory to report to the Consultant in Communicable Diseases Control. They include:

- Tuberculosis
- Malaria
- Meningitis
- Meningococcal sepsis.

[Q: 3747] OnExamination 2012 - Ethics and law

You are completing a list of cremation form 5s for patients in the hospital where you work.

You examine one form where the junior doctor has completed the cause of death as stroke, but the patient appears to have fallen at home. The husband wants to arrange cremation as soon as possible.

Apparently the junior doctor is working nights and has gone home, so you cannot easily get hold of him to question him further.

Which of the following is true with respect to completion of the form?

- 1- Completion of form 5 to show that examination of the case has been "adequate" would be acceptable
- 2- It is acceptable in this case not to question the doctor
- 3- Medical referees will not mind if you have not contacted the doctor
- 4- When completing form 5 you must only be reasonably sure that the patient suffered a stroke

- 5- You should wait to complete the form until the doctor is available to answer questions

Answer & Comments

Answer: 5- You should wait to complete the form until the doctor is available to answer questions

Doctors are now instructed that form 5 should always be completed after questioning the doctor who completed form 4 except under exceptional circumstances, that is, only if the doctor is seriously ill.

Unavailability of the doctor is not an appropriate excuse, so quite clearly in this case you should wait to complete the form.

The other major principle with respect to completion of form 5 is that you must be absolutely sure that the cause of death is correct.

Ministry of Justice cremation guidelines

[Q: 3748] OnExamination 2012 - Ethics and law

A female patient of yours unfortunately goes into premature labour at 23 weeks. The fetus is not viable. She wishes to have the fetal remains cremated.

Which of the following is true with respect to legal aspects of this case?

- 1- Cremation of the remains is not subject to the Cremation Act
- 2- Only a pathologist is allowed to complete form 4
- 3- Only form 4 need be completed
- 4- Only form 5 need be completed
- 5- The case must be discussed with the coroner

Answer & Comments

Answer: 1- Cremation of the remains is not subject to the Cremation Act

Cremation of fetal remains under 24 weeks is not subject to the Cremation Act.

As such, forms 4 and 5 should not be completed.

In spite of this, most crematoria are happy to make arrangements to cremate fetal remains.

Where body parts are removed at post mortem, arrangements for cremation of these are normally made by the pathology service.

Ministry of Justice cremation guidelines

[Q: 3749] OnExamination 2012 - Ethics and law

You are working for the elderly care team in the hospital when an 82-year-old woman under your care is found dead by the nursing staff in the early hours of the morning.

She was not resuscitated due to a history of severe chronic obstructive pulmonary disease (COPD).

You have written the cause of death as old age and you complete cremation form 4.

Which of the following is true with respect to completion of the forms?

- 1- Civil proceedings have been taken against doctors who have inappropriately completed form 5
- 2- Old age is usually not an acceptable cause of death for cremation purposes when completing form 4
- 3- The consultant who heads up the team may complete form 5
- 4- The locum staff grade who qualified three years ago in India may sign form 5
- 5- Your brother who is a house officer on another team at the hospital may sign form 5

Answer & Comments

Answer: 2- Old age is usually not an acceptable cause of death for cremation purposes when completing form 4

A key point with respect to completing form 4 is that the cause of death must be accurately established.

Whilst old age may be acceptable when certifying for a burial, it is not accepted by cremation referees.

The latest guidelines for doctors include specific instructions that members of the same hospital team as the physician completing part 4 must not complete the form, nor may partners in the same GP practice complete the form either.

Additionally, relatives of the patient are forbidden from completing either form 4 or 5, and relatives of the doctor who completes form 4 cannot complete form 5.

Ministry of Justice cremation guidelines

[Q: 3750] OnExamination 2012 - Ethics and law

A 23-year-old female attends clinic for a routine appointment regarding a six month history of occasional fits.

She has seen the neurologists who have diagnosed idiopathic epilepsy and have prescribed lamotrigine. She informs you that she is doing well with this medication and has not had a fit for two months.

She has been told that she must stop driving but you have seen that she drove to attend the clinic. You discuss this with her and insist that she stops driving to which she informs you that she had stopped driving but since she is fit free she must continue to drive because of her employment.

Which of the following is the most appropriate action to take in these circumstances?

- 1- Inform patient that you will notify the DVLA
- 2- Inform patient that you will notify the police
- 3- Inform the epilepsy clinic that she is still driving and allow them to deal with this issue.
- 4- You cannot inform any external body due to patient confidentiality.
- 5- Your only action is to write in the notes that the patient has been repeatedly warned but chose to ignore advice as she presents no serious risk in view of her epilepsy control.

Answer & Comments

Answer: 1- Inform patient that you will notify the DVLA

The law is quite clear on such issues regarding epilepsy and the ability to drive.

If the diagnosis is confirmed the patient must stop driving and inform the DVLA regarding the diagnosis.

If the patient continues to drive despite advice to the contrary then the doctor has a duty of care to society overriding confidentiality to the patient and may inform the DVLA.

[Q: 3751] OnExamination 2012 - Ethics and law

A 78-year-old male dies and is found by his children the following morning (after having seen him alive the night before). His GP attends to certify him dead.

The patient had a known history of ischaemic heart disease and was treated in the local hospital where angiography performed nine months previously for angina had revealed some insignificant coronary artery disease of two vessels for which medical therapy was deemed most appropriate. He had also been

diagnosed eight years previously with diabetes mellitus for which he took metformin and gliclazide.

He had seen the practice nurse two weeks ago for review of his diabetes. One month ago he had seen the diabetologists for his annual review and had seen the cardiologists approximately six months ago. He had last seen a partner in the practice six weeks ago for advice concerning driving licence registration.

The family are keen to have a death certificate issued and proceed to cremation. They do not want any post mortem examination.

Which of the following is true with regard to issuing of a death certificate in this scenario?

- 1- The certifying doctor may issue a death certificate
- 2- The death needs to be referred to the coroner
- 3- The diabetologist can certify the death
- 4- The partner in the practice may issue a death certificate
- 5- The practice nurse can certify the death

Answer & Comments

Answer: 2- The death needs to be referred to the coroner

A death certificate may be completed if the practitioner has seen the deceased within 14 days of the death (28 days in NI). In this case the patient had been seen six weeks previously by the partner.

Consequently, and in view of the sudden death, the coroner should be informed, although he may decide that in the circumstances reported, the doctor may be able to issue a death certificate stating ischaemic heart disease if he deems it appropriate, and on the balance of advice given to him.

[Q: 3752] OnExamination 2012 - Ethics and law

Withholding the truth about a patient's illness is a violation of which of the following?

- 1- Autonomy
- 2- Beneficence
- 3- Informed consent
- 4- Infringement of the Human Rights Act
- 5- The Bolam principle

Answer & Comments

Answer: 1- Autonomy

By not informing the patient about all the aspects of their illness we are removing their ability to make decisions for themselves. In effect we, and their relatives, are making the decisions for them. This is the removal of their autonomy.

Informed consent relies upon the patient being provided with the information that is generated from the investigations to which he has consented. Justice implies going beyond one's own feelings, prejudices, and desires to find an appropriate balance among conflicting interests.

The Bolam principle is the basis upon which a doctor's actions are judged such that they would be considered appropriate and reasonable to those actions that would be performed by a responsible body of their peers in similar circumstances.

[Q: 3753] OnExamination 2012 - Ethics and law

A 75-year-old woman presents with a 6-12 Hz tremor in the hands.

The tremor initially started in the right hand, but has worsened over time and now involves both hands. The tremor has also slowly increased in severity. She remembers that her father suffered from 'the shakes' as well.

Which additional finding would suggest a diagnosis of essential tremor rather than Parkinson's disease?

- 1- Action tremor
- 2- Bradykinesia
- 3- Kinetic tremor
- 4- Postural tremor
- 5- The tremor increases with emotional stress

Answer & Comments

Answer: 1- Action tremor

One of the main characteristics of essential tremor is that the tremor is an action tremor. Action tremor constitutes both postural and kinetic tremor.

Answer B is incorrect as bradykinesia is a key feature of Parkinson's disease and not essential tremor.

Answer C is incorrect as essential tremor has both kinetic and postural tremor which constitutes an action tremor. Parkinson's disease has a resting tremor.

Answer D is incorrect because essential tremor has both postural and kinetic tremor which constitutes an action tremor. Parkinson's disease has a resting tremor.

Answer E is incorrect because the tremor in both Parkinson's disease and essential tremor may worsen with emotional stress.

http://www.ninds.nih.gov/disorders/tremor/detail_tremor.htm

[Q: 3754] OnExamination 2012 - Ethics and law

A 70-year-old man is brought to the memory clinic by his wife.

The patient appears calm and composed and does not have any complaints. His wife said over the last three months her husband lost

his way back home in the evening three times and was brought back by the neighbours.

Choose the appropriate diagnosis from the following list.

- 1- Alcoholism
- 2- Chronic subdural haematoma
- 3- Depression
- 4- Dementia
- 5- Transient global amnesia

Answer & Comments

Answer: 4- Dementia

Because the confusion occurred in the evenings, alcoholism is a possibility and should be explored in the history. However, it is not mentioned in the scenario, hence alcoholism is unlikely.

Chronic subdural haematoma and depression would present with gradual and persistent change in personality without any recovery. However, chronic subdural haematoma and depression should be excluded in all cases of suspected dementia.

Transient global amnesia almost always occurs as a single episode.

[Q: 3755] OnExamination 2012 - Ethics and law

Which of the listed common conditions can mimic the signs and symptoms of an acute stroke?

- 1- Cardiac arrest
- 2- Hypoglycaemia
- 3- Hypothyroidism
- 4- Pneumothorax
- 5- Stokes-Adams attacks

Answer & Comments

Answer: 2- Hypoglycaemia

Hypoglycaemia is common and mimics signs and symptoms of acute stroke; hence determination of blood glucose and treatment of hypoglycaemia is part of the initial assessment of a patient with symptoms or signs of acute stroke.

Signs of cardiac arrest are

Unresponsiveness

No breathing

No pulse and

Absence of other signs of circulation.

Stokes-Adams attacks present with sudden short lasting loss of consciousness resulting in falls.

Hypothyroidism and pneumothorax are obviously false answers.

[Q: 3756] OnExamination 2012 - Ethics and law

Which of the following drugs would improve prognosis in heart failure?

- 1- ACE - I
- 2- Atenolol
- 3- Digoxin
- 4- Furosemide
- 5- Nitrates

Answer & Comments

Answer: 1- ACE - I

Furosemide is effective in improving symptoms secondary to volume overload, it does not improve prognosis.

However, the randomised Aldactone evaluation study (RALES) trial has shown 30% reduction in mortality when spironolactone was added to conventional treatment.

Atenolol has not been evaluated in the management of heart failure.

Carvedilol, metoprolol and bisoprolol have been proven through trials to improve prognosis in heart failure.

Trials showed digoxin neither increased nor decreased total cardiovascular mortality because reduction in deaths due to progressive heart failure was balanced by an increase in deaths due to ischaemia and arrhythmia as a result of digoxin therapy.

Hydralazine and isosorbide nitrate in combination have been shown to be as effective as ACE-I for improving symptoms, but these drugs do not alter prognosis.

[Q: 3757] OnExamination 2012 - Ethics and law

Which one of the following deaths should be reported to the coroner?

- 1- A 52-year-old male with a long history of alcohol abuse is admitted with confusion. He dies two days later with hepatic failure.
- 2- A 62-year-old male with a two year history of severe dementia is admitted from a nursing home with fever and breathlessness. He dies three days later with pneumonia.
- 3- A 69-year-old male with pneumoconiosis is admitted with fever and breathlessness. He dies two days later from pneumonia.
- 4- A 72-year-old male is admitted with a myocardial infarction and dies 48 hours following admission.
- 5- A 73-year-old female who had undergone a hip replacement two months previously presents with severe chest pain and breathlessness. She is diagnosed with pulmonary embolism but dies.

Answer & Comments

Answer: 3- A 69-year-old male with pneumoconiosis is admitted with fever and breathlessness. He dies two days later from pneumonia.

Increasingly emphasis is placed on the appropriate reporting of deaths particularly from the enquiries into Shipman and the Coroners Reform Bill. In fact, it is the duty of the Registrar of Births, Deaths and Marriages to report a death to the coroner but doctors need to be aware of the circumstances in which a death should be reported.

These include:

The cause of death is unknown.

The deceased was not seen by the certifying doctor either after death or within 14 days before death.

The death was violent or unnatural.

The death may be due to an accident.

The death may be due to self neglect or neglect by others.

The death may be the result of industrial illness or due to the persons employment (as with the 69-year-old male above, pneumoconiosis being an industrial disease).

The death may be due to an abortion.

The death occurred during an operation or before recovery from anaesthesia.

The death may be suicide.

The death occurred during or shortly after being taken into police custody.

The MDU have published a guide to Coroners Inquiries which is free to members:

www.the-mdu.com

[Q: 3758] OnExamination 2012 - Ethics and law

A 22-year-old female is admitted following severe injuries sustained in a road traffic accident. She is communicative but in shock with low blood pressure and tachycardia.

You realise that without a transfusion she will die but she informs you that she has recently

become a Jehovah's Witness and that she adamantly refuses transfusion, despite knowledge that she could die.

Her distraught parents tell you that she has only recently joined the Jehovah's Witnesses and implore you to transfuse her, as they insist that she does not know her own mind.

Together with other intervention which she permits, what is the most appropriate action regarding possible transfusion?

- 1- Declare her incompetent and transfuse
- 2- Do not transfuse even if it means that she will die
- 3- Get immediate psychiatric intervention to section her and then transfuse
- 4- Transfuse immediately, irrespective of the patient's wishes
- 5- Wait until she becomes unconscious and then get consent from her parents to transfuse

Answer & Comments

Answer: 2- Do not transfuse even if it means that she will die

The patient appears competent and has elected to refuse the transfusion. Despite the parents' protestation you must respect the patient's wishes if, as seems likely here, she is making a reasoned judgement.

If the patient refuses the transfusion then even if she slips into unconsciousness you are not permitted to treat with transfusion even if it is in her best interests.

[Q: 3759] OnExamination 2012 - Ethics and law

Which of the following defines ethics?

- 1- Codes and statements of professional organisations of physicians about appropriate conduct
- 2- Obedience to the law

- 3- Prescriptions found in Scripture
- 4- The study of morality
- 5- The study of the human conscience

Answer & Comments

Answer: 4- The study of morality

Ethics are defined as the study of morality/the philosophical study of moral values and rules.

[Q: 3760] OnExamination 2012 -
Ethics and law

In which of the following cases is the individual's right to autonomy violated?

- 1- A Jehovah's witness patient with symptomatic anaemia who refuses blood transfusion
- 2- An athlete who seeks a second opinion
- 3- An infant whose parents elect for surgery to correct a congenital heart defect
- 4- An older man whose physician and family coerce him into having foot surgery
- 5- An older woman who refuses to undergo back surgery

Answer & Comments

Answer: 4- An older man whose physician and family coerce him into having foot surgery

Autonomy refers to an individual's right to be self-governing.

Although the procedures may be in the best interests of the patient, if the patient refuses and this refusal is informed, then the doctor or relatives cannot coerce that person into having the procedure.

[Q: 3761] OnExamination 2012 - Psychiatry

A 17-year-old male is brought to clinic as his parents are concerned about changes in his behaviour.

Which of the following suggest a diagnosis of schizophrenia?

- 1- Auditory hallucinations with clouding of consciousness
- 2- Feelings of panic in buses and shops
- 3- Grandiose ideations
- 4- Incongruity of affect
- 5- Memory impairment

Answer & Comments

Answer: 4- Incongruity of affect

Incongruity of affect is emotion inappropriate to circumstances. Although not one of the first-rank symptoms of schizophrenia, it is consistent with the diagnosis.

Auditory hallucinations are typical, especially third person, but clouding of consciousness is not typical.

The panic in crowds suggests an anxiety disorder and grandiose ideations suggest mania.

[Q: 3762] OnExamination 2012 - Psychiatry

The parents of an 8-year-old boy have noticed increased blinking and throat clearing.

He had normal development and is doing well at school until recently when he was sent home for shouting swear words during assembly.

His parents have not noticed any change in behaviour, with normal appetite, sleep and energy. He takes no medication. His father suffers with partial seizures.

What is the likely diagnosis?

- 1- Epilepsy
- 2- Huntington's disease
- 3- Rett syndrome
- 4- Tourette syndrome
- 5- Wilson's disease

Answer & Comments

Answer: 4- Tourette syndrome

Tourette syndrome presents before 18 years of age and many children grow out of it.

The criteria for diagnosis require multiple motor and one or more vocal tics, showing themselves over a year, with not more than three consecutive months tic free. The motor tics often have a build up that the patient is aware of, like an itch. Commonly they involve blinking, throat clearing or shoulder shrugging.

Although his father has epilepsy this is unlikely to be epilepsy as the shouting of swear words is a typical vocal tic of Tourette's.

Huntington's disease is a neurodegenerative genetic disorder that is autosomal dominant. The features are of choreiform movements, problems with coordination and walking, behavioural and psychiatric problems. The disease leads eventually to dementia and premature death.

Rett syndrome predominantly affects females and is a neurodevelopment disorder of the grey matter. The sufferers have small hands and feet with deceleration of head growth. Many patients are epileptic, display repetitive hand movements, rarely develop speech and also have GI problems, such as constipation.

Wilson's disease is an autosomal recessive condition which causes build up of copper in the body. Copper accumulates in the liver and brain. This results in hepatitis, liver failure or cirrhosis. Accumulation in the brain can result in behavioural changes, depression, seizures,

parkinsonism, however the initial sign is usually increased clumsiness.

[Q: 3763] OnExamination 2012 - Psychiatry

A 32-year-old man visits his GP complaining that he is totally depressed and fixated by the loss of his wife and child who were killed by a hit and run driver around one year earlier.

He says that he has taken to drinking large quantities of alcohol every day and occasionally even smoking heroin in an attempt to forget what happened and stop the memories of the event playing back in his mind. He cannot hold down a job because he finds it impossible to concentrate, is constantly irritable and hardly sleeps at night. He attends the clinic with his mother who tells you that he has not cried since the event.

Which of the following is the most appropriate treatment for him?

- 1- Cognitive therapy
- 2- Diazepam
- 3- Mirtazapine
- 4- Paroxetine
- 5- Phenelzine

Answer & Comments

Answer: 1- Cognitive therapy

This man has post traumatic stress disorder (PTSD) as a result of the horrific event which led to the death of his wife and child.

NICE guidelines support the use of trauma focussed cognitive behavioural therapy as the mainstay of therapy.

Other options include:

Eye movement desensitisation

Reprocessing and relaxation techniques.

Drug therapies are very much second line therapy for PTSD, although they may be of

value in treating associated co-morbidities such as depression, with selective serotonin reuptake inhibitors (SSRIs) being recommended by NICE as first line drug therapy.

Clinicians are warned, however, that increased agitation may lead to suicidal ideation during the first few weeks of treatment.

[Q: 3764] OnExamination 2012 - Psychiatry

A 45-year-old female with chronic schizophrenia was recently converted to a new antipsychotic agent. She presented two weeks later with a sore throat and fever.

Her full blood count shows:

Haemoglobin 12.5 g/dl(11.5-16.5)

White cell count $1.3 \times 10^9/L$ (4-11)

Platelets $135 \times 10^9/L$ (150-400)

What drug is she likely to have commenced?

- 1- Clozapine
- 2- Haloperidol
- 3- Olanzapine
- 4- Quetiapine
- 5- Risperidone

Answer & Comments

Answer: 1- Clozapine

Clozapine is associated with agranulocytosis and granulocytopenia in approximately 1-2% of patients, which can result in fatal sepsis. The mechanism through which this happens remains unclear. In order to safeguard against harm a UK Clozaril Patient Monitoring System ensures strict monitoring of all patients on this treatment. A white cell count with differential is checked prior to treatment, then weekly for the first 18 weeks, then two weekly from week 18 to 52, and then four weekly after one year of clozapine with stable

blood results. They are then checked for four weeks after discontinuation of treatment.

Olanzapine has been associated with agranulocytosis in the form of case reports in the literature. However, unlike clozapine, this link is not well established.

None of the other medications listed are commonly associated with agranulocytosis.

[Q: 3765] OnExamination 2012 - Psychiatry

A 22-year-old woman presented following an overdose. She had had an argument with her boyfriend and had then driven to an isolated country lane where she had swallowed 20 paracetamol tablets and a bottle of wine.

Which one of the following is the strongest predictor that she may later make a fatal suicide attempt?

- 1- Female gender
- 2- Location of the suicide attempt
- 3- Taking alcohol with the tablets
- 4- The argument with the boyfriend
- 5- The number of tablets

Answer & Comments

Answer: 2- Location of the suicide attempt

About one-third of people who attempt suicide will repeat the attempt within one year, and about 10% of those who threaten or attempt suicide eventually do kill themselves.

There are certain characteristics that have been found in those who are more likely to repeat an attempted suicide.

These characteristics include

Age of 45 or more

The fact of being male

A previous attempt which resulted in hospital admission

Problems with drugs or alcohol

Suffering from a personality disorder

Living alone (especially if separated, divorced, or widowed)

Previous history of psychiatric treatment

Criminal record

Unemployment

Lower social class.

Relational pathology, for example an ongoing difficulty with her relationship with her boyfriend, is also a recognised factor for repeat suicide attempts. The fact that we do not know whether she has ongoing relationship problems means that we cannot class this as the strongest predictor of future suicidal intent.

Thus, the fact that she drove to an isolated area where there was little chance of her being found suggests that this is a serious attempt at suicide which predicts future suicidal intent.

[Q: 3766] OnExamination 2012 - Psychiatry

A 70-year-old woman had a major depressive disorder which was unresponsive to antidepressant medication.

Which one of the following statements is correct?

- 1- Associated dementia is unlikely
- 2- Electroconvulsive therapy (ECT) is likely to improve her mood
- 3- If she recovers, relapse is unlikely
- 4- The risk of suicide is low
- 5- Underlying physical illness is unlikely

Answer & Comments

Answer: 2- Electroconvulsive therapy (ECT) is likely to improve her mood

Depression in the elderly is a widespread problem that is often not diagnosed and frequently under-treated.

Depression can also be a sign of a medical problem. It may be complicated by brain disorders associated with the ageing process such as Alzheimer's disease.

Suicide risk in the elderly is an important consideration and is at least as common as in younger age groups. Relapse of depressive symptoms is common in the elderly.

ECT is indicated in patients who derive no benefit from antidepressant medication.

[Q: 3767] OnExamination 2012 - Psychiatry

A 30-year-old man is admitted to the psychiatric unit after abnormal behaviour in a police cell. He told police that there was a conspiracy against him and he began behaving irrationally.

Thirty six hours after admission to the psychiatric unit the patient has a grand-mal seizure.

Which of the following is the most likely cause of the seizure?

- 1- Amphetamine withdrawal
- 2- Hypercalcaemia
- 3- Idiopathic epilepsy
- 4- LSD withdrawal
- 5- Withdrawal from barbiturates

Answer & Comments

Answer: 5- Withdrawal from barbiturates

LSD withdrawal is not reported to cause seizures, and amphetamine withdrawal is

associated with depression, intense hunger and lethargy, but not with seizures.

There is nothing to suggest hypercalcaemia in this patient as the cause for fits but hyponatraemia associated with water intoxication following ecstasy abuse would be a possibility.

Barbiturate withdrawal in an habitual abuser is a well recognised cause of fits together with the altered behaviour.

It is unlikely, given the circumstances, that this is idiopathic epilepsy, although it remains a differential diagnosis.

[Q: 3768] OnExamination 2012 - Psychiatry

Which of the following statements concerning the causation and dynamics of schizophrenia is correct?

- 1- Decline in IQ scores during childhood may be a harbinger of psychotic symptoms in adults.
- 2- In monozygotic twins the risk of the second twin developing schizophrenia if the first is affected is of the order of 10%
- 3- Schizophrenia is commoner in higher socio-economic groups
- 4- Schizophrenia is commoner in individuals in unstable relationships
- 5- The lifetime risk of developing schizophrenia if one parent is affected is of the order of 50%

Answer & Comments

Answer: 4- Schizophrenia is commoner in individuals in unstable relationships

Schizophrenia occurs twice as often in unmarried and divorced people as in married or widowed individuals. Furthermore, people with schizophrenia are eight times more likely to be in the lowest socioeconomic groups.

These statistics are likely to reflect the alienating effects of this disease rather than any causal relationship or risk factor associated with poverty or a single life.

Nevertheless, low income and poverty may increase the risk for exposure to biological factors (for example, infections or toxins) or social stressors that could trigger the illness in susceptible people.

Monozygotic twins may have a 50% concordance and 10% of offspring may be affected suggesting strong inheritance.

[Q: 3769] OnExamination 2012 - Psychiatry

Which of the following features is most strongly suggestive of a diagnosis of somatisation disorder?

- 1- Below average intelligence
- 2- Male gender
- 3- Having a close relative with a physical illness
- 4- Many admissions to medical wards as an adult
- 5- Symptoms of a bizarre nature

Answer & Comments

Answer: 4- Many admissions to medical wards as an adult

Somatisation means the expression of psychological distress into bodily complaints for which medical help is sought.

Somatisation disorder is characterised by multiple, recurrent and changing symptoms for which no physical cause can be found. These typically last for over two years, and can be associated with multiple medical admissions. Patients refuse to accept advice or reassurance that no physical cause can be found. Functional impairment is common due to the nature of the symptoms and resultant behaviour. It affects women much more than

men, and is accompanied by a tendency to excessive drug use.

Common symptoms include gastrointestinal (belching, pain, vomiting, nausea), skin (burning, itching, tingling) and sexual and menstrual complaints. They are not usually bizarre.

There is no recognised link with IQ or a family history of disease.

Other forms of persistent somatisation include hypochondriasis, dysmorphophobia and psychogenic pain.

[Q: 3770] OnExamination 2012 - Psychiatry

Regarding puerperal psychosis which of the following statements is true?

- 1- Often takes the form of schizophrenia
- 2- Recurrence of puerperal psychosis in subsequent pregnancies is the rule
- 3- The onset is usually insidious
- 4- The prognosis is usually good
- 5- Usually begins after the second week of the puerperium

Answer & Comments

Answer: 4- The prognosis is usually good

Puerperal psychosis is a relatively rare complication of childbirth affecting 1 - 2 per 1000 births. (Postnatal depression is much commoner affecting 100 - 150 women per 1000 births).

Puerperal psychosis is a mood disorder with features of loss of contact with reality, hallucinations, thought disorder and abnormal behaviour. It usually presents rapidly in the first month but most often starts in the first week.

Prognosis is good.

Read more SIGN guideline 60.

[Q: 3771] OnExamination 2012 - Psychiatry

Which of the following is considered indicative of an abnormal grief reaction?

- 1- Adopting mannerisms of the deceased
- 2- Anger
- 3- Denial
- 4- Duration longer than 12 months
- 5- Hallucinations

Answer & Comments

Answer: 4- Duration longer than 12 months

Worden (1991) gives four headings for 'complicated grief reactions'

Chronic grief reactions

Delayed reactions

Exaggerated grief reactions and

Masked grief reactions.

There are huge variations between individuals and cultures and the question of what is normal and abnormal grief needs to be approached with sensitivity. In the west, six months is considered average for grief, most authorities would consider greater than 12 months abnormal.

Anger and denial have been identified by Kubler-Ross (1969) as part of her five 'stages' of normal grief (although even Kubler-Ross herself now states that the concept of a neat linear progression through grief is simplistic).

Hallucinations and adopting the deceased's mannerisms can occur in the early stages of grief and would not be considered abnormal on their own.

[Q: 3772] OnExamination 2012 - Psychiatry

A 63-year-old man was found collapsed.

A department of psychiatry outpatient card was found in his jacket, together with a bottle of procyclidine tablets.

He was febrile (38.2°C), conscious but unresponsive to commands. The blood pressure was 160/105 mmHg and there was marked muscle rigidity.

What is the most likely diagnosis?

- 1- Acute catatonic schizophrenia
- 2- Bacterial meningitis
- 3- Cerebral malaria
- 4- Neuroleptic malignant syndrome
- 5- Procyclidine overdose

Answer & Comments

Answer: 4- Neuroleptic malignant syndrome

The symptoms are typical of neuroleptic malignant syndrome (NMS).

NMS is characterised by:

Fever

Muscular rigidity

Altered mental status

Autonomic dysfunction.

Procyclidine is used to treat the Parkinsonian side effects of neuroleptics; its presence in the patient's pocket implies that he was taking neuroleptics.

Signs of procyclidine overdose include:

Agitation

Confusion

Sleeplessness lasting up to 24 hours or more

Pupils are dilated and unreactive to light.

Visual and auditory hallucinations and tachycardia have also been reported.

Further reading

Neuroleptic malignant syndrome information service

[Q: 3773] OnExamination 2012 - Psychiatry

A 34-year-old female presents with swallowing difficulties.

She says that she feels a "lump in her throat" that is worse in the morning. There is no associated pain and she had a steak sandwich for supper. Her family feels that she has lost weight since her partner left her eight months ago.

On meeting her you note sweaty palms and tremor. She has a BMI 22.

What is the most likely diagnosis?

- 1- Anorexia nervosa
- 2- Barrett's oesophagus
- 3- Globus hystericus
- 4- Hyperthyroidism
- 5- Pheochromocytoma

Answer & Comments

Answer: 3- Globus hystericus

Despite this woman's weight loss there is unlikely to be an organic cause, as she is able to swallow food boluses. There is no evidence of acid reflux to produce Barrett's oesophagus.

Hyperthyroidism may present with weight loss and a sensation of fullness in the throat, plus tachycardia and tremor. However the weight loss appears to be associated with a life change (stressor) and the "lump in her throat" alters throughout the day.

Anorexia nervosa is diagnosed when BMI is less than 17, there is altered body image and avoidance of food.

Phaeochromocytoma may give weight loss, sweating and tremor, however it would not give a strange sensation in the neck, and

there would be complaints of palpitations or anxiety with tachycardia.

Globus hystericus is part of the anxiety disorders and thought to be due to somatisation. In this case a stressor is the loss of her partner and this has led to anxiety symptoms and altered sensation in her neck.

This sensation is fluctuating and there is no mechanical problem. It is a diagnosis of exclusion and therefore it would be necessary to rule out some of the other mentioned diagnoses first.

[Q: 3774] OnExamination 2012 - Psychiatry

A 65-year-old gentleman presents with a two month history of memory impairment.

His wife has noticed that he often needs prompting for daily tasks and can be quite drowsy on some days. His memory fluctuates but is not necessarily better in the morning or evening. He has also started to act bizarrely, talking to himself and reaching out for things that do not appear to be there.

On examination he has cog-wheeling with a mask-like face and shuffling gait.

What is the most likely diagnosis?

- 1- Alzheimer's disease
- 2- Lewy body dementia
- 3- Normal pressure hydrocephalus
- 4- Parkinson's disease
- 5- Wilson's disease

Answer & Comments

Answer: 2- Lewy body dementia

Lewy body dementia is a mixture of Alzheimer's disease with Parkinson's disease.

Lewy body dementia is distinguished from dementia with Parkinson's by the time frame, as the cognitive impairment occurs within 12 months of Parkinsonism.

The main features are fluctuating cognition and alertness from hour to hour, visual hallucinations (usually of animal or human, and the patient may have insight into these hallucinations) and motor features of Parkinson's disease.

Wilson's disease is an autosomal recessive condition which causes build up of copper in the body. Copper accumulates in the liver and brain. This results in hepatitis, liver failure or cirrhosis. Accumulation in the brain can result in behavioural changes, depression, seizures, parkinsonism, however the initial sign is usually increased clumsiness.

This gentleman has change in cognition and hallucinations as well as being 65-years-old, making Wilson's less likely.

Parkinson's disease causes motor signs such as pill-rolling tremor, cog-wheel rigidity, shuffling gait, low voice, reduced arm swing and reduced expression (mask-like), as well as falls due to postural hypotension. Patients can develop memory impairment usually one year after motor symptoms.

Normal pressure hydrocephalus presents with urinary incontinence and urgency, gait disturbance (magnetic gait with reduced foot clearance, an increased preponderance to fall backwards and problems particularly with curbs) and dementia (frontal lobe characteristics).

Alzheimer's disease is dementia with loss of memory over a period of time, with behavioural changes often aggression, and withdrawal from social/family life. There is reduced attention, with language, problem solving and perception affected (MMSE important test). There are no motor signs.

[Q: 3775] OnExamination 2012 - Psychiatry

Which of the following might be a reason for someone to be judged to lack mental capacity using the functional test of capacity (for

example, as used by the Mental Capacity Act 2005)?

- 1- Contradicting previously expressed wishes
- 2- Inability to understand the relevant information
- 3- Irrational decision making
- 4- Loss of hearing aid
- 5- Presence of mental illness

Answer & Comments

Answer: 2- Inability to understand the relevant information

The Mental Capacity Act 2005 uses a functional test of capacity.

In the case of the MCA, the specific tests applied are that the individual must show an ability to

Understand and retain the relevant information

Weigh their options (and see the consequences of any choice)

Communicate their choice.

Although the Mental Capacity Act is specific to England and Wales, the functional test of capacity is used internationally and forms the basis for legislation in Scotland, USA and most English-speaking nations.

Whilst previously expressed wishes should be taken into account, these usually form part of a 'best interests' assessment, which occurs after capacity has been evaluated. The issue of previously expressed wishes would not be a determinant under functional tests of capacity, and mentally capacitated individuals have a right to contradict previously expressed wishes.

Using widely accepted criteria for the functional test of capacity, the answer is inability to understand the relevant information.

Irrational decision making is called the 'rational outcome' approach - it is not a functional test of capacity and is not used, for example, in the Mental Capacity Act as it is too subjective.

Although 'communicating choice' is a criterion in the MCA, loss of a hearing aid would not be considered a sufficiently good reason to judge lack of capacity. The onus is on the doctor to alleviate any remediable communication problem prior to assessing capacity.

Many functional tests of capacity have a 'diagnostic hurdle', that is, the presence of mental illness might be a reason to trigger a mental capacity assessment, but mental illness itself is no reason automatically to assume lack of capacity - this would be a 'status' test of capacity.

[Q: 3776] OnExamination 2012 - Psychiatry

Which of the following demographic factors is associated with a higher than normal risk of completed suicide?

- 1- Age below 35 years
- 2- Female sex
- 3- Marriage
- 4- Socio-economic group 1
- 5- Unemployment

Answer & Comments

Answer: 5- Unemployment

Deliberate self harm (DSH) is significantly more common than completed suicide.

For every 100 patients admitted to hospital following self harm, one will complete suicide within a year (Key topics in psychiatry 1996).

The demography and risk factors for deliberate self harm are often different from those for suicide.

Unemployment and low socio-economic groups are consistently associated with a higher risk of suicide than those with employment or in higher socio-economic groups.

Older males are considered at higher risk of completed suicide whilst younger women are considered the 'typical' profile for someone committing self harm (however DSH rates in younger men have risen considerably in recent years, closing the gap).

Marriage is one of the strongest protective factors against completed suicide, with men tending to benefit more than women.

[Q: 3777] OnExamination 2012 - Psychiatry

Which of the following is a biological feature of depression?

- 1- Derailment
- 2- Early morning waking
- 3- Low mood
- 4- Negativism
- 5- Thought block

Answer & Comments

Answer: 2- Early morning waking

Symptoms of depression include low mood, negative ideation including suicidality, biological symptoms and in severe cases, psychosis.

Biological symptoms include early morning waking, loss of appetite and libido, although many textbooks include poor concentration, anhedonia and easy fatigability as biological symptoms.

Biological symptoms are considered specific to depression but may lose specificity when a patient has symptoms of medical illness.

Derailment and thought block are forms of thought disorder associated with schizophrenia.

Negativism is a symptom of catatonia.

Only early morning waking is a biological feature of depression.

[Q: 3778] OnExamination 2012 - Psychiatry

A 25-year-old male is brought to casualty by his family.

He has become isolative, and is talking in a disorganised fashion. He complains that his thoughts are 'leaking' from his head and can be read by all.

What is the likely diagnosis?

- 1- Borderline (emotionally unstable) personality disorder
- 2- Delirium
- 3- Persistent delusional disorder
- 4- Psychotic depression
- 5- Schizophrenia

Answer & Comments

Answer: 5- Schizophrenia

The age and sex of the patient fits the demographic profile of schizophrenia. The symptom of thought broadcasting is one of Schneider's first rank symptoms, which are widely regarded as specific to schizophrenia. Therefore option E is the correct answer.

Option A, borderline personality disorder, may present with symptoms mimicking psychosis, for example, pseudo-hallucinations, but not thought broadcasting.

Options B, C and D may present with psychotic symptoms but not thought broadcasting.

[Q: 3779] OnExamination 2012 - Psychiatry

A 34-year-old woman comes to the clinic complaining of chronic fatigue. She has felt increasingly tired over the past few months, and just walking her children to school makes her so tired that she has to lie down for a rest for two to three hours. She has even had to give up her part time job selling cosmetics.

There have also been increasing headaches, and occasional palpitations.

Her only past medical history of note includes irritable bowel syndrome. On examination her BP is normal at 115/70 mmHg, pulse is 62 and regular and her BMI is 22 kg/m².

Cardiovascular, respiratory and abdominal examination is normal.

Investigations show

Haemoglobin 12.0 g/dl (11.5-16.0)

White cell count 5.6 x 10⁹/L (4-11)

Platelets 187 x 10⁹/L (150-400)

Serum Sodium 137 mmol/l (135-146)

Serum Potassium 4.2 mmol/l (3.5-5)

Creatinine 90 µmol/l (79-118)

Thyroid stimulating hormone 1.2 mu/l (0.5-5.0)

Glucose 5.0 mmol/l (4.5-5.6)

Calcium 2.3 mmol/l (2.20-2.67)

Which of the following is the most appropriate intervention?

- 1- Amitriptyline
- 2- Fluoxetine
- 3- Graded exercise therapy
- 4- Melatonin
- 5- Multi-vitamin replacement

Answer & Comments

Answer: 3- Graded exercise therapy

This woman is suffering from chronic fatigue syndrome as evidenced by her history, including:

Prolonged periods of rest after relatively minor exercise

Recurrent headaches

and normal physical examination and basic haematological and biochemical investigations.

There is little evidence to support the use of pharmacological therapies, although co-existent depression may be best managed with a non-sedating selective serotonin reuptake inhibitor (SSRI) such as fluoxetine, and sleep disorders with amitriptyline. Melatonin may be helpful in the paediatric population.

The best evidence for benefit in chronic fatigue syndrome comes from trials examining the use of graded exercise therapy, and as such should be considered in this case.

[Q: 3780] OnExamination 2012 - Psychiatry

A 27-year-old woman complained of palpitations, breathlessness and chest pain, radiating to the left arm.

These symptoms had developed six weeks previously, after she had witnessed her father dying from a myocardial infarction.

In the past 10 years she had been investigated for abdominal pain, headaches, joint pains, and dyspareunia, without serious cause being found for these symptoms.

What is the most likely diagnosis?

- 1- Depressive episode
- 2- Factitious disorder
- 3- Generalised anxiety disorder
- 4- Obsessive compulsive disorder
- 5- Somatisation disorder

Answer & Comments

Answer: 5- Somatisation disorder

Although the brief scenario does not have quite enough criteria to fulfil a diagnosis there is enough to make somatisation disorder the most likely answer.

Somatisation disorder is characterised by multiple recurring pains and gastrointestinal, sexual, and pseudo-neurologic symptoms that occur over a period of years.

To meet the diagnostic criteria for somatisation disorder, the patient's physical complaints must not be intentionally induced and must result in medical attention or significant impairment in social, occupational, or other important areas of functioning.

By definition, the first symptoms appear in adolescence and the full criteria are met by 30 years of age.

Of all the other disorders 'factitious disorder' would seem the least likely.

The other three are possible explanations but not as likely as somatisation.

[Q: 3781] OnExamination 2012 - Psychiatry

A 35-year-old man with a known history of acute intermittent porphyria because he carries a medical emergency card is brought to the Emergency department by the police; he has been violent with acute psychosis.

Which of the following sedatives would be the safest to use in this circumstance?

- 1- Chloral hydrate
- 2- Chlorpromazine
- 3- Diazepam
- 4- Haloperidol
- 5- Phenobarbitone

Answer & Comments

Answer: 2- Chlorpromazine

Phenothiazines have antiemetic and antipsychotic properties, making them the medication of choice for acute porphyria episodes.

[Q: 3782] OnExamination 2012 - Psychiatry

A 57-year-old man is admitted following a serious suicide attempt. He tries to leave hospital stating he is going to 'do the job properly'.

Under advice from your consultant, you use a section 5(2) holding power of the Mental Health Act (MHA) 2007 to detain him.

Which of the following is permitted in a section 5(2)?

- 1- Conversion to section 2 (assessment order) or 3 (treatment order) of the MHA 2007
- 2- Detention for 28 days
- 3- Leave if agreed with the responsible clinician
- 4- Transfer to a psychiatric hospital
- 5- Treatment with an antidepressant

Answer & Comments

Answer: 1- Conversion to section 2 (assessment order) or 3 (treatment order) of the MHA 2007

The MHA 2007 affects mainly England and Wales but other mental health acts in other countries have similar short term holding orders.

The purpose of the holding power is simply to keep an in-patient in hospital for the purpose of formal assessment, therefore formal assessment to a section 2 or 3 is not just permissible, it is strongly encouraged (option A).

As a holding order, the power of a 5(2) is limited - it does not allow any treatment, physical or psychiatric, that needs to be done under the Mental Capacity Act if the patient does not consent (option E).

An individual cannot be given leave or transferred either, unless there is a medical emergency (options C and D).

A 5(2) lasts a maximum of 72 hours (section 2 is for 28 days [option B]), but it would be considered bad practice for it to get to the maximum time limit without a formal assessment. (See MHA Code of Practice.)

[Q: 3783] OnExamination 2012 - Psychiatry

A 42-year-old man presented with confusion following a seizure.

He has a history of epilepsy and is also known to the community psychiatry team.

Examination reveals that he has a temperature of 37°C, BP 138/84 mmHG, coarse tremor and a pulse of 90 bpm.

Which of the following is the most likely underlying diagnosis?

- 1- Benzodiazepine overdose
- 2- Carbamazepine toxicity
- 3- Lithium toxicity
- 4- Neuroleptic malignant syndrome
- 5- Tricyclic overdose

Answer & Comments

Answer: 3- Lithium toxicity

The tremor, seizure and confusion should raise the possibility of lithium toxicity which is the condition that best fits this clinical picture.

eMedicine: Lithium toxicity

[Q: 3784] OnExamination 2012 - Psychiatry

A 67-year-old man is referred as an emergency by his general practitioner.

The night before he attempted to smother his wife whilst he was fast asleep. The following day, whilst oblivious to the potentially dangerous situation, he reports remembering dreaming about fighting a bear. His father had experienced a similar event some years before being diagnosed with Parkinson's disease.

Which of the following is the most likely diagnosis?

- 1- Adult attention deficit hyperactivity disorder (ADHD)
- 2- Lewy body dementia
- 3- Night terrors
- 4- REM sleep behaviour disorder
- 5- Schizophrenia

Answer & Comments

Answer: 4- REM sleep behaviour disorder

Rapid eye movement (REM) sleep behaviour disorder, often associated with the violent re-enacting of dreams, occurs when the normal atonicity of REM sleep is lost.

There is an association with the later development of movement disorders and these can be predicted by a number of years.

Making the situation safe is paramount but treatment with clonazepam is the intervention of choice.

[Q: 3785] OnExamination 2012 - Psychiatry

An 82-year-old male with longstanding Alzheimer's dementia presents as his carers are concerned about his increased episodes of aggression. Physically he is well.

Which is the most appropriate treatment for his aggressive outbursts?

- 1- Diazepam
- 2- Quetiapine
- 3- Risperidone
- 4- Temazepam
- 5- Valproate

Answer & Comments

Answer: 2- Quetiapine

Risperidone used to be a favourite treatment for aggression/agitation in dementia but recent studies indicate that it is associated with an increased mortality and a threefold increased risk of stroke.

Valproate is widely used for its calming effects in this situation but although widely used there is little evidence of the efficacy of valproate.

Valproic acid for agitation in dementia
Cochrane Database Syst Rev. 2004;(2):CD003945

Haloperidol may be associated with cardiac arrhythmias, and its use is now discouraged for long term use.

The other options are associated with more prominent adverse effects.

[Q: 3786] OnExamination 2012 - Psychiatry

A 27-year-old female presents with persistent fatigue, myalgia, poor concentration and irritability following a flu-like illness 18 months previously.

A diagnosis of chronic fatigue syndrome (CFS) is made.

What is the appropriate initial management of this patient?

- 1- Antidepressants
- 2- Cognitive behavioural therapy

- 3- ECT
- 4- Psychoanalysis
- 5- Reversion therapy

Answer & Comments

Answer: 2- Cognitive behavioural therapy

In general, in order to receive a diagnosis of chronic fatigue syndrome, a patient must satisfy two criteria:

Have severe chronic fatigue of six months or longer duration with other known medical conditions excluded by clinical diagnosis.

Concurrently have four or more of the following symptoms:

Substantial impairment in short term memory or concentration

Sore throat

Tender lymph nodes

Muscle pain

Multi-joint pain without swelling or redness

Headaches of a new type pattern or severity

Unrefreshing sleep

Post-exertional malaise lasting more than 24 hours.

(source CDC).

There is a RCP report on CFS from 1996.

Low dose antidepressants are used in the treatment of CFS, but the suggested first line therapy should include cognitive behavioural therapy, if access to this service is available.

[Q: 3787] OnExamination 2012 - Psychiatry

An 18-year-old woman presented with a history of 15 kg weight loss in the previous four months. She has been amenorrhoeic for some months.

On examination she had fine lanugo hair and a blood pressure of 110/60 mmHg.

Which one of the following laboratory results would support the most likely clinical diagnosis?

- 1- High plasma follicle stimulating hormone (FSH) concentration
- 2- High serum ferritin concentration
- 3- Low plasma cortisol concentration
- 4- Low plasma testosterone concentration
- 5- Suppressed thyroid stimulating hormone (TSH) concentration

Answer & Comments

Answer: 5- Suppressed thyroid stimulating hormone (TSH) concentration

The question alludes to a patient with anorexia nervosa.

Anorexia is associated with functional hypogonadotrophic hypogonadism with low FSH and luteinising hormone (LH) levels.

Cortisol levels may be increased but are typically within the 'normal range'. They may however, may fail to suppress with dexamethasone.

Plasma testosterone levels are normal in females with anorexia.

Basal levels of TSH may be depressed in anorexia, though T4 and T3 may be normal.

Ferritin levels are low in a state of malnutrition.

[Q: 3788] OnExamination 2012 - Psychiatry

A 28-year old man complained of voices which told him to self-harm.

He was unemployed, having dropped out of university two years previously.

Dependence on which of the following is the most likely cause?

- 1- Alcohol
- 2- Amphetamines
- 3- Benzodiazepines
- 4- Gamma-hydroxybutyrate (GHB)
- 5- Opiates

Answer & Comments

Answer: 2- Amphetamines

The question suggests that the patient is suffering from actions experienced as made or influenced by external agents, a Schneider's first rank symptom.

Amphetamines are known to lead to drug induced schizophrenia.

Benzodiazepines are not known to induce schizophrenia, but there are reports of auditory hallucinations on benzodiazepine withdrawal.

GHB is not associated with drug induced schizophrenia; opiates may be associated with hallucinations, but not Schneider's first rank symptoms.

One must be aware of the potential dual-diagnosis scenario; that is the patient who is dependent on a drug, but who also has schizophrenia, which may have been precipitated by drug-use or stress, but which is not drug-induced per se.

[Q: 3789] OnExamination 2012 - Psychiatry

A 50-year-old business man who has been drinking heavily for at least two years, states that he drinks alcohol on his way into work as he suffers from anxiety attacks.

Which one of the following statements is true regarding these episodes?

- 1- They are imagined
- 2- They are not accompanied by tremor
- 3- They are still present after drinking

- 4- They will deteriorate after three weeks of abstinence from alcohol
- 5- They will improve after three weeks of abstinence from alcohol

Answer & Comments

Answer: 5- They will improve after three weeks of abstinence from alcohol

This patient has anxiety symptoms due to withdrawal from alcohol.

The typical symptoms include agitation, fever, sweats and tremor which are relieved by alcohol. These symptoms usually peak after about 72 hours and may last a week or more but should have improved after three weeks.

[Q: 3790] OnExamination 2012 - Psychiatry

With respect to symptoms of withdrawal related to chronic alcohol use, which of the following statements is correct?

- 1- Benzodiazepines are ineffective in the treatment of seizures secondary to alcohol withdrawal, due to cross tolerance with ethanol a type A gamma-aminobutyric acid receptor
- 2- Carbamazepine is as effective as benzodiazepines in the acute treatment of the symptoms of alcohol withdrawal
- 3- Phenytoin is an effective treatment for seizures related to alcohol withdrawal
- 4- Withdrawal reflects enhanced neurotransmission in type A gamma-aminobutyric acid pathways
- 5- Withdrawal reflects reduced neurotransmission in N-methyl-D-aspartate pathways

Answer & Comments

Answer: 2- Carbamazepine is as effective as benzodiazepines in the acute treatment of the symptoms of alcohol withdrawal

Carbamazepine at a starting dose of 800 mg per 24 hours has been shown to be as effective as oxazepam in the treatment of acute alcohol withdrawal.

Phenytoin is not effective in the treatment of alcohol withdrawal-related seizures.

Alcohol withdrawal reflects the damping of neurotransmission through type A gamma-aminobutyric pathways, and enhanced neurotransmission through N-methyl-D-aspartate pathways.

[Q: 3791] OnExamination 2012 - Psychiatry

A patient on the ward is diagnosed with schizophrenia.

You are asked to speak with the mother and father of the patient. They ask you about prognostic features of schizophrenia.

Which of the following features of their son's illness, character, and lifestyle, which they raise are poor prognostic indicators in schizophrenia?

- 1- A precipitating cause
- 2- High intelligence
- 3- Strong family history
- 4- Sudden onset of symptoms
- 5- Unstable social background

Answer & Comments

Answer: 3- Strong family history

Unstable social background predisposes, but does not confer poor prognosis in schizophrenia.

A strong family history is related to prognosis in schizophrenia.

Insidious onset confers a poor prognosis, and a precipitating cause and high intelligence are favourable prognostic indicators.

[Q: 3792] OnExamination 2012 - Psychiatry

You are asked to consent a patient for electroconvulsive therapy (ECT).

Which of the following is not a hazard of ECT?

- 1- Amnesia
- 2- Crush fracture of the vertebral bodies
- 3- Induction of cardiac arrhythmia
- 4- Induction of dementia
- 5- Memory loss

Answer & Comments

Answer: 4- Induction of dementia

Side effects of ECT are rare.

Over the course of ECT, it may be more difficult for patients to remember newly learned information, though this difficulty disappears over the days and weeks following completion of the ECT course.

Some patients also report a partial loss of memory for events that occurred during the days, weeks, and months preceding ECT. While most of these memories typically return over a period of days to months following ECT, some patients report longer lasting problems with recall of these memories.

Other individuals report improved memory ability following ECT, because of its ability to remove the amnesia sometimes associated with severe depression.

Cardiac arrhythmia may be stimulated by the electrical shock of ECT.

Musculoskeletal injury has been reported after ECT, but with adequate anaesthetisation, this is rare.

Dementia is an organic illness which is not induced by ECT.

[Q: 3793] OnExamination 2012 - Psychiatry

A 45-year-old woman presents with polydipsia and polyuria. She says that she is having difficulty sleeping as she is constantly thirsty, drinking many glasses of water during the day, and passing urine excessively at night.

She has a history of anxiety and depression and is currently managed with fluoxetine to control her symptoms. She also has a history of mild hypertension, which is controlled with ramipril 5 mg.

On examination her BP is 135/70 mmHg, and a general physical examination is normal.

Investigations show

Hb 13.1 g/dl (11.5-16.5)

WCC $5.6 \times 10^9/L$ (4-11)

PLT $203 \times 10^9/L$ (150-400)

Na 134 mmol/l (135-146)

K 4.0 mmol/l (3.5-5)

Cr 90 $\mu\text{mol/l}$ (79-118)

Glucose 5.6 mmol/l (4.5-5.6)

Ca 2.2 mmol/l (2.2-2.67)

Plasma osmolality 275 mOsm/l (282-295)

Which of the following is the most likely diagnosis?

- 1- Cranial diabetes insipidus
- 2- Hyperglycaemia-related polyuria
- 3- Nephrogenic diabetes insipidus
- 4- Psychogenic polydipsia
- 5- Syndrome of inappropriate antidiuretic hormone hypersecretion (SIADH)

Answer & Comments

Answer: 4- Psychogenic polydipsia

This patient has a previous history of anxiety and depression and has been prescribed

fluoxetine, which may invoke SIADH, but there is no evidence of that here.

The low sodium seen is likely to result from water overload due to excess fluid intake. Her glucose and calcium are not in the range to precipitate thirst and polyuria.

In this case, cognitive therapy is likely to have the greatest impact on her symptoms.

[Q: 3794] OnExamination 2012 - Psychiatry

A 50-year-old woman presents with multiple recurrent and frequently changing symptoms that are 'functional' in nature (somatisation disorder).

Which of the following statements concerning her management is correct?

- 1- Antidepressant medication is unlikely to help
- 2- An understanding of her early childhood experiences is necessary
- 3- Her progress will be slower if she thinks her doctors do not believe her
- 4- Medical staff need to minimise their contact with her relatives
- 5- She should be persuaded to understand that her symptoms are psychological

Answer & Comments

Answer: 3- Her progress will be slower if she thinks her doctors do not believe her

This is quite a tough question. The College has asked about somatisation disorder in at least four recent examinations so they must think it is quite important.

Knowledge of early childhood experiences is not necessary

Depression is often found so antidepressives are useful

Relatives should be involved and

Empathy, not persuasion, is the key to management.

[Q: 3795] OnExamination 2012 - Psychiatry

A 24-year-old male presents with shortness of breath, chest pains and cough.

He is a smoker of 10 pack/years and occasionally uses cocaine and ketamine.

He uses PRN salbutamol inhaler for asthma diagnosed in childhood. He has been treated by his GP for chest infections four times in the past seven months, with different courses of antibiotics.

On examination he has a white exudate on his tongue and throat. His examination is otherwise normal. The nursing staff tells you that his saturations drop to 74% on room air when walking to the bathroom.

What test will confirm your diagnosis?

- 1- Chest x ray
- 2- ECG
- 3- Peak expiratory flow
- 4- Sputum culture
- 5- Sputum immunofluorescence

Answer & Comments

Answer: 5- Sputum immunofluorescence

This gentleman has candidiasis of his throat that may be due to his inhaler usage but given his other symptoms and history may well be secondary to HIV infection.

He has recurrent chest infections and now symptoms compatible with PCP infection (dry cough, chest pains, desaturation on exertion, normal chest examination).

The only test that will confirm this is sputum immunofluorescence. Severe cases should be treated with steroids in addition to co-trimoxazole or pentamidine.

Chest x ray classically shows perihilar interstitial shadowing, but this can occur with other infections and therefore is not conclusive evidence.

ECG will be unremarkable.

Peak expiratory flow (PEF) may show reduction in his ability due to exacerbation of asthma in the presence of infection, but again it is not a diagnostic test.

A straightforward sputum culture will not diagnose *Pneumocystis carinii*.

[Q: 3796] OnExamination 2012 - Psychiatry

A 27-year-old woman is suffering with headaches that have occurred daily for the past three months.

They occur at different times of the day and affect the frontal and occipital areas. She has no neck stiffness or rash. She does not have any visual symptoms.

She has noticed cramps and tingling in her lips and fingers associated with palpitations and a feeling of suffocation. She takes no medication.

She is concerned because her father died from glioblastoma 12 months ago.

What is the likely cause of her headaches?

- 1- Anxiety neurosis
- 2- Benign intracranial hypertension
- 3- Glioblastoma
- 4- Nelson's syndrome
- 5- Neurosarcoidosis

Answer & Comments

Answer: 1- Anxiety neurosis

This lady's symptoms do not have any 'red flags' so it is unlikely to be organic in cause.

Benign intracranial hypertension (BIH) and glioblastoma would give her a headache that

worsened with coughing or sneezing and might be associated with visual symptoms.

Neurosarcoidosis can present with nerve palsies, deficiencies of the pituitary function or character changes/psychosis. This lady does not have any other symptoms pointing towards sarcoid.

Nelson's syndrome is pituitary enlargement following adrenalectomy for Addison's disease.

This lady's symptoms fit with an anxiety neurosis. She has symptoms of anxiety, headache, hyperventilation (tetany and tingling) and palpitations, related to the stressor of her father's death.

[Q: 3797] OnExamination 2012 - Psychiatry

A 70-year-old man with vascular dementia is recuperating on the stroke rehabilitation ward after a middle cerebral artery infarct.

Despite several conversations he does not realise he is in hospital but is usually settled, accepts medication and is not on any neuroleptics; however on two nights in the last week he has tried to leave the ward at night, having to be forcibly returned. His doctors and nurses agree his rehabilitation is in his best interests, although likely to take weeks.

What is the best medico-legal framework for his management?

- 1- Common law
- 2- DOLS (deprivation of liberty safeguarding)
- 3- Mental Capacity Act
- 4- Mental Health Act
- 5- Nothing - he should be allowed to leave

Answer & Comments

Answer: 2- DOLS (deprivation of liberty safeguarding)

DOLS assessments require a doctor approved under the Mental Health Act and a best interest assessor to ascertain whether

The patient is over the age of 18

Has a mental illness as defined under the Mental Health Act

Lacks capacity

Is being detained in his or her best interests and that

The DOLS order will not conflict with a pre-existing arrangement under either the MHA or MCA.

The Mental Capacity Act (option C) has now superseded common law (option A); both allow treatment of a mentally incapacitated adult in emergency circumstances, where such treatment is in their best interests.

However the emergency powers of the MCA are designed only for short term crises, one of the reasons DOLS was introduced.

The Mental Health Act (option D) is designed primarily to enforce psychiatric treatment and is neither necessary nor sufficient for his physical medical treatment.

However the DOLS legislation (option B), which has been added to the MCA, is designed for exactly such a situation, that is, a mentally incapacitated adult whose consent to remain is dubious.

E is not an option - you have a duty of care to vulnerable patients, and a court of law would take a dim view of any doctor who allowed such a patient to put himself at risk.

[Q: 3798] OnExamination 2012 - Psychiatry

You see a 45-year-old man in clinic with symptoms of akathisia from his antipsychotic medication.

You discuss reducing his antipsychotic but he insists that every time medication is reduced

below the current dosage his delusions get much worse.

What would be your next best therapeutic manoeuvre?

- 1- Antimuscarinic (for example, procyclidine)
- 2- Benzodiazepine (for example, clonazepam)
- 3- Beta-blocker
- 4- Dopamine agonist (for example, pramipexole)
- 5- Vitamin E

Answer & Comments

Answer: 2- Benzodiazepine (for example, clonazepam)

This man suffers from akathisia, a well-documented side effect of dopamine blockade.

According to a Cochrane review (Oct 1999), benzodiazepines (traditionally clonazepam) have the best research evidence in combating this unpleasant side effect.

B-blockers, (option C) are often recommended but according to a 2004 Cochrane review, there is insufficient evidence to support their use.

Antimuscarinics (option A) are often prescribed, mainly because they are used for other motor side effects of dopamine blockade but again a Cochrane review (Oct 2006) concluded the evidence was poor and there are in fact case reports of antimuscarinics worsening symptoms.

There is no firm evidence to support the use of pramipexole (option D) and akathisia is listed as a side effect, so it cannot be recommended. Pramipexole is licensed for the treatment of restless legs syndrome, a condition superficially similar to akathisia.

Finally vitamin E (option E) is often recommended in the treatment of early

tardive dyskinesia (although evidence of efficacy is mixed).

[Q: 3799] OnExamination 2012 - Psychiatry

You are asked to review a 35-year-old man who was transferred from a psychiatric ward a week ago with unexplained pyrexia.

Nurses say he is deteriorating: on examination he has reduced conscious level, a temperature of 38.5°C, BP 90/ 50 mmHg, pulse 110 bpm. There is generalised muscle stiffness but no neck stiffness and no focal neurology.

Basic screening bloods in casualty show mild leucocytosis and dehydration with CRP 50. The rest of the FBC and biochemistry including liver function tests are essentially normal. Infection screen - including CXR, mid-stream urine (MSU) and blood cultures - is negative.

Which of the following would be the best investigation to perform next?

- 1- Brain CT (computerised tomography)
- 2- Creatine kinase (CK)
- 3- Lumbar puncture
- 4- Repeat blood culture
- 5- Sputum m, c and s (microscopy, culture and sensitivity)

Answer & Comments

Answer: 2- Creatine kinase (CK)

The history is strongly suggestive of neuroleptic malignant syndrome. This is an idiopathic drug reaction associated with initiation or adjustment of neuroleptic medication, particularly dopamine blockers such as antipsychotics. Primary diagnostic features are altered conscious level, autonomic instability and muscular rigidity with raised creatine kinase (CK).

A CK level (option B) can give an answer within a matter of hours: given the history of muscular rigidity, it should be the next investigation.

Options C to E are reasonable investigations in the situation but will all take time, it would be hard to justify their priority over a simple test like a CK.

A CT (option A) is unlikely to give a useful answer in the absence of focal neurology.

[Q: 3800] OnExamination 2012 - Psychiatry

Which of the following is the most useful imaging modality of the brain when investigating Lewy body dementia?

- 1- CT
- 2- DaTscan™ (dopamine transporter scan)
- 3- HMPAO PET
- 4- MRI
- 5- Skull x ray

Answer & Comments

Answer: 2- DaTscan™ (dopamine transporter scan)

Conventional imaging is used mainly to rule out other causes of cognitive impairment.

Alzheimer's disease may show as atrophy (medial temporal atrophy is considered most characteristic of Alzheimer's). Vascular dementia may show as scattered ischaemia. Both these changes are more easily detected on MRI than CT. Lewy body dementia (LBD) is poorly served by conventional imaging.

DaTscan™, (option B), uses radio ligands to bind to dopamine receptors in the brain. The sensitivity of the DaTscan for the diagnosis of DLB is 88% and specificity is 100 % (Walker et al 2007). Its main drawback is expense.

Lewy body dementia has no specific identifying features on CT (option A) or MRI (option D).

Some studies suggest HMPAO PET can be used to distinguish between LBD and other dementias but it is not as specific as DaTscan.

Skull x ray (option E) cannot show the soft tissues of the brain and has little value in diagnosing any dementia.

[Q: 3801] OnExamination 2012 - Psychiatry

A 24-year-old man is admitted to the Emergency department via the police. He was found trying to kick in the windows of a local department store.

His flatmates tell you that he has been acting increasingly strangely over the past few weeks, and has covered the inside of his room with silver paper.

On examination he looks agitated, his BP is 155/80 mmHg, and his pulse is 90. He tells you to stop the voices in the room from commenting on his actions and his personality.

Investigations show

Hb 12.9 g/dl(13.5-18)

WCC $6.7 \times 10^9/L$ (4-11)

PLT $256 \times 10^9/L$ (150-400)

Na 139 mmol/l (135-146)

K 4.5 mmol/l (3.5-5)

Cr 120 mmol/l (79-118)

Urine Positive for cannabinoids

Which of the following is the most likely diagnosis?

- 1- Drug-induced psychosis
- 2- Encephalitis
- 3- Hypomania
- 4- Personality disorder
- 5- Schizophrenia

Answer & Comments

Answer: 5- Schizophrenia

This patient is displaying a number of the 'first-rank' symptoms of schizophrenia. For the purpose of the MRCP examination these are considered diagnostic of schizophrenia.

In this case the patient has third person auditory hallucinations with running commentary. Covering his room with silver paper may be an attempt to stop thought broadcasting.

The presence of urinary cannaboids may make you think about drug-induced psychosis. However the presence of first-rank symptoms precludes this diagnosis. In addition, cannabis has been linked with the development of schizophrenia, and cannabis may be used by patients suffering from schizophrenia to self-medicate.

The first-rank symptoms also make encephalitis, hypomania and personality disorder unlikely.

For treatment of acute psychosis, haloperidol or a rapidly dissolving formulation of olanzapine may be of value. Other atypical antipsychotics such as risperidone are usually used for maintenance treatment.

[Q: 3802] OnExamination 2012 - Psychiatry

A 72-year-old man presents to the Emergency department. He has an unshakable belief that he has stomach cancer and has taken an overdose of paracetamol tablets after making a decision to end it all.

He has been off his food for the past six months, having lost 6 kg. He is finding it difficult to fall asleep and wakes in the early hours of the morning at about 4 am. He sees nothing positive in his current situation and has lost all interest in work.

On examination he looks unkempt, has clearly not washed or shaved for many days.

Investigations show:

Haemoglobin 13.1 g/dl(13.5-18)

White cell count $7.2 \times 10^9/L$ (4-10)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (134-143)

Potassium 4.7 mmol/l (3.5-5)

Creatinine 99 $\mu\text{mol/l}$ (60-120)

ESR 5 (<10)

Which of the following is the most likely diagnosis?

- 1- Carcinoma of the stomach
- 2- Depression
- 3- Hypomania
- 4- Personality disorder
- 5- Schizophrenia

Answer & Comments

Answer: 2- Depression

This man shows:

Depressed mood

No interest or pleasure

Weight loss

Early morning waking.

This all fits with an episode of major depression, the delusion that he has stomach cancer being consistent with this picture.

He has a normal full blood count and an ESR just outside the normal range. This makes actual underlying carcinoma of the stomach unlikely.

After initial treatment of his paracetamol overdose, medication for his depression should take into account risk of future overdose.

Tricyclic anti-depressants are likely to carry significantly more risk than selective

serotonin reuptake inhibitors (SSRIs) in overdose.

[Q: 3803] OnExamination 2012 - Psychiatry

A 21-year-old history student has returned to university after a field trip to the US. His girlfriend has called the student health service as he has begun dressing in ceremonial robes and has announced to her that he is the dean of the faculty and orders her to wait on his every need.

He has been known to use cannabis in the past and has used ecstasy on several other occasions. Additionally, he has been using some caffeine tablets to help him stay up at night to prepare an essay for submission and has been suffering from worsening headaches over the past few weeks.

The student health service persuades him to come in for an urgent appointment, where on examination, he is wearing a very bright shirt and trousers, and a black academic robe and mortar board hat. His BP is 112/70 mmHg, his pulse is 80 and regular.

Physical examination is unremarkable but you identify both pressure of speech and flight of ideas on mental state examination.

Investigations show

Haemoglobin 13.1 g/dl (13.5-8)

White cell count $6.1 \times 10^9/L$ (4-10)

Platelets $209 \times 10^9/L$ (150-400)

Sodium 142 mmol/l (134-143)

Potassium 4.6 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (60-120)

Which of the following is the most likely diagnosis?

- 1- Drug induced psychosis
- 2- Intracerebral mass lesion
- 3- Mania
- 4- Personality disorder

5- Schizophrenia

Answer & Comments

Answer: 3- Mania

This man's grandiose delusions, flight of ideas and pressure of speech fit best with a diagnosis of mania. The headaches and illicit drug use are distractors from the most likely diagnosis.

The objective is to control this patient's symptoms rapidly, and ensure safety for both himself and his partner.

Treatment options include:

Mood stabilisers such as:

Lithium

Sodium valproate

Carbamazepine

Atypical anti-psychotics, such as risperidone

Benzodiazepines.

[Q: 3804] OnExamination 2012 - Psychiatry

A 52-year-old male is admitted after taking an overdose.

Which single feature best suggests a high risk of future suicide?

- 1- Ingestion of alcohol with the overdose drug
- 2- Ingestion of more than one drug
- 3- Ingestion of more than 100 tablets
- 4- Making plans before the overdose to avoid discovery
- 5- Previous history of overdose

Answer & Comments

Answer: 4- Making plans before the overdose to avoid discovery

The effort to conceal the overdose suggests a serious intent to commit suicide, more so than the other options given.

Previous history of overdoses (rather than parasuicide - as we do not know exactly what was taken, he could have taken an overdose of cod liver oil) does not necessarily imply a more serious intent.

Other factors that would imply a more sinister intent would be male, elderly with mental illness.

[Q: 3805] OnExamination 2012 - Psychiatry

Which of the following is a typical side effect of olanzapine?

- 1- Akathisia
- 2- Hypoadrenalism
- 3- Hypoglycaemia
- 4- Macroglossia
- 5- Steven-Johnson syndrome

Answer & Comments

Answer: 1- Akathisia

Akathisia is a typical side effect associated with the use of the atypical antipsychotic olanzapine.

Others include

Agranulocytosis

Hyperprolactinaemia

Hyperglycaemia

Depression

Anxiety.

[Q: 3806] OnExamination 2012 - Psychiatry

A 22-year-old man consults his GP complaining of redness and itching on his face

and hands.

He has regularly visited another GP for similar complaints within the last two years and has been signed off on sick leave from employment as a builder. He is in receipt of benefits and reports that he is in the process of making an insurance claim for loss of earnings.

He says that there was one ointment that cured the problem but he had not been able to find any proprietary medication that works. Examination showed no skin lesions and no apparent rash.

What is the most likely diagnosis?

- 1- Conversion disorder
- 2- Delusional disorder
- 3- Malingering
- 4- Munchausen syndrome
- 5- Obsessive compulsive disorder

Answer & Comments

Answer: 3- Malingering

In somatoform disorders, both illness production and motivation are unconscious drives.

In malingering, as suggested here, the patient consciously fakes or claims to have a disorder in order to attain a specific gain (for example, financial).

Munchausen syndrome is manifested by a chronic history of multiple hospital admissions and willingness to receive invasive procedures.

[Q: 3807] OnExamination 2012 - Psychiatry

A 45-year-old woman has, approximately four hours ago, taken an unknown quantity of amitriptyline tablets that were being prescribed for her depression. She is feeling drowsy, agitated and has a dry mouth.

An ECG shows wide QRS complexes with arrhythmias.

Blood gas analysis revealed:

pH 7.2 (7.36-7.44)

paO₂ 10 kPa(11.3-12.6)

paCO₂ 4 kPa(4.7-6.0)

What is the most appropriate treatment?

- 1- Activated charcoal
- 2- Gastric lavage
- 3- Haemodialysis
- 4- Intravenous insulin
- 5- Intravenous sodium bicarbonate

Answer & Comments

Answer: 5- Intravenous sodium bicarbonate

There is no specific treatment for tricyclic antidepressant poisoning.

500 ml of 1.26% sodium bicarbonate should be used to treat arrhythmias, hypotension and significant ECG abnormalities to a pH of 7.50-7.55 in tricyclic antidepressant overdose, even in the absence of acidosis.

[Q: 3808] OnExamination 2012 - Psychiatry

A 41-year-old female is brought into the Emergency department after taking an uncertain quantity of paracetamol two hours previously and trying to hang herself.

She becomes agitated and insists that she wants to go home immediately. You judge that she is at high risk of suicide.

Which of the following is the most appropriate course of action for this patient?

- 1- Ask her to sign a 'discharge against medical advice' form and let her go
- 2- Call the duty psychiatrist, and with other staff in the emergency department attempt to restrain her under common law until they arrive

- 3- Call the duty psychiatrist, but let the patient go if she insists and the duty psychiatrist does not arrive in time to see her
- 4- Call the hospital security services, restrain her and sedate her
- 5- Detain her under section 5(2) of the Mental Health Act

Answer & Comments

Answer: 2- Call the duty psychiatrist, and with other staff in the emergency department attempt to restrain her under common law until they arrive

In an Emergency department the suicidal patient who declines to be admitted for observation and treatment should be managed as follows:

Ensure that a member of staff stays with them at all times

Call the duty psychiatrist if they attempt to abscond before or during psychiatric assessment.

The staff of the Emergency department have a duty under common law to restrain the patient.

If a patient who is already being nursed on a medical, surgical or obstetric ward, or in a high dependency or intensive care unit, develops a mental illness (or has an exacerbation of a pre-existing disorder), their physician or surgeon can authorise their compulsory detention for up to 72 hours under section 5(2) of the Mental Health Act.

[Q: 3809] OnExamination 2012 - Psychiatry

A 81-year-old male presents with difficulty coping at home and is found to be depressed.

Which one of the following statements regarding this patient is correct?

- 1- Electroconvulsive therapy (ECT) would be contraindicated if he had a previous cerebrovascular accident
- 2- He is unlikely to have had previous episodes of depression
- 3- Monoamine oxidase inhibitors are the most appropriate treatment for this patient
- 4- Somatic symptoms would be an unexpected feature
- 5- Suicide would be unlikely in a patient of this age

Answer & Comments

Answer: 1- Electroconvulsive therapy (ECT) would be contraindicated if he had a previous cerebrovascular accident

ECT may result in seizures, cerebral ischaemia and cardiac arrhythmias.

In the elderly confusion and falls may also occur.

Somatic complaints and previous depressive illness are common.

Suicide rates in males of this age group are significantly above the national average.

Monoamine oxidase (MAO) inhibitors are not the drugs of choice in the elderly due to the risk of side effects including severe hypertension.

[Q: 3810] OnExamination 2012 - Psychiatry

A 76-year-old male attends clinic with his wife who states that her husband has become disinterested and withdrawn.

Which of the following would favour a diagnosis of dementia rather than depression?

- 1- Agitation
- 2- Poor short term memory

- 3- Reduced libido
- 4- Self-reported concern of poor memory
- 5- Urinary incontinence

Answer & Comments

Answer: 5- Urinary incontinence

Urinary incontinence would be particularly unusual in association with a depressive episode and would be far more typical of dementia. Almost invariably a patient with dementia will develop incontinence as the disease progresses. This is not due to urinary tract pathology, but more due to impaired mobility, reduced manual dexterity, mental capacity and motivation. All these factors combine to make continence incredibly difficult.

The other symptoms may be found in dementia, particularly impaired memory and concern over memory deficits.

[Q: 3811] OnExamination 2012 - Psychiatry

A 40-year-old ex-footballer presents requesting treatment for alcoholism and is prescribed disulfiram.

What is the mode of action of disulfiram?

- 1- Decreases severity of alcohol withdrawal
- 2- Helps alcoholics to drink safely
- 3- Inhibits acetaldehyde dehydrogenase activity
- 4- Inhibits alcohol dehydrogenase activity
- 5- Reduces the desire for alcohol

Answer & Comments

Answer: 3- Inhibits acetaldehyde dehydrogenase activity

Alcohol is mainly metabolised in the liver to acetaldehyde by alcohol dehydrogenase.

Acetaldehyde is then oxidised to acetate by acetaldehyde dehydrogenase (AcDH).

Disulfiram irreversibly inhibits the oxidation of acetaldehyde by competing with the cofactor nicotinamide adenine dinucleotide (NAD) for binding sites on AcDH.

The increased acetaldehyde levels are thought to produce the unpleasant side effects associated with acetaldehyde syndrome such as headaches, nausea, flushing, etc.

[Q: 3812] OnExamination 2012 - Psychiatry

All of the following lead to the increased risk of developing schizophrenia or a schizophrenic-like illness, except which?

- 1- Amphetamine addiction
- 2- Being brought up in an institution
- 3- Sibling with schizophrenia
- 4- Social Class V
- 5- Temporal lobe epilepsy

Answer & Comments

Answer: 2- Being brought up in an institution

Nurture in an institution does not predispose individuals to schizophrenia.

Schizophrenia is however more common in social classes IV and V.

The lifetime risk of developing schizophrenia in the UK is 1%. If there is an affected sibling the risk increases to 8-10%.

Temporal lobe epilepsy may cause hallucinations mimicking schizophrenia, and amphetamines may cause a state resembling hyperactive paranoid schizophrenia with hallucinations.

[Q: 3813] OnExamination 2012 - Psychiatry

A 21-year-old woman is known to suffer from anorexia nervosa.

Which of the following metabolic disturbances would be a characteristic finding?

- 1- A decrease in cortisol levels
- 2- An increase in LH levels
- 3- Hyperkalaemia
- 4- Impaired glucose tolerance
- 5- Raised androgen levels

Answer & Comments

Answer: 4- Impaired glucose tolerance

Malnutrition is another cause of diabetes. (Can you name the others? In addition to type 1 and type 2, gestational or post pancreatitis / pancreatectomy, read more about the others).

Cortisol and growth hormone levels are elevated.

Luteinising hormone (LH) and follicle-stimulating hormone (FSH) would be low and LH response to luteinising-hormone releasing hormone (LHRH) is impaired when weight loss is severe.

Hypokalaemia (not hyperkalaemia) may be seen.

Also there may be:

- Hypoalbuminaemia
- Anaemia
- Leukopenia
- Raised serum carotene.

[Q: 3814] OnExamination 2012 - Psychiatry

Which of the following features is

characteristic of early Alzheimer's disease?

- 1- Ataxic gait
- 2- Impaired short term memory
- 3- Myoclonic jerks
- 4- Urinary incontinence
- 5- Visual hallucinations

Answer & Comments

Answer: 2- Impaired short term memory

Alzheimer's disease is characterised early in the disease by short term memory loss.

The other features listed here would suggest an alternative diagnosis such as:

Normal pressure hydrocephalus (gait ataxia and urinary incontinence)

Creutzfeldt-Jakob disease (myoclonic jerks)

Delirium or vascular dementia (visual hallucinations).

[Q: 3815] OnExamination 2012 - Psychiatry

A 17-year-old girl presents after having ingested 50 of her mother's fluoxetine tablets, approximately five hours previously.

Which one of the following clinical features is compatible with this history?

- 1- Heart rate of 30 beats per minute
- 2- Pupillary constriction
- 3- QRS duration of 120 ms (<100)
- 4- Respiratory rate of six breaths per minute
- 5- Vomiting

Answer & Comments

Answer: 5- Vomiting

Unlike the tricyclic antidepressants, fluoxetine, like many of the SSRIs are safe in overdose, causing very few effects.

Rarely, reports would suggest that tachycardia can occur together with

Tremor

Drowsiness

Nausea

Vomiting.

Pupillary constriction or respiratory suppression suggests opiates.

Prolonged QRS complex is consistent with TCA overdose.

[Q: 3816] OnExamination 2012 - Psychiatry

A 17-year-old female is referred with a six month history of amenorrhoea and weight loss, for which no organic cause can be found.

Which of the following features would support a diagnosis of anorexia nervosa (AN)?

- 1- Delusion of being overweight
- 2- Delusions of poisoning
- 3- Hypergonadotrophic hypogonadism
- 4- Hypotrichosis
- 5- Watery diarrhoea

Answer & Comments

Answer: 1- Delusion of being overweight

Features of AN include:

- A phobic avoidance of normal weight
- Relentless dieting
- Self-induced vomiting
- Laxative use
- Excessive exercise
- Amenorrhoea
- Lanugo hair
- Hypotension
- Denial

- Concealment
- Overperception of body image
- Enmeshed families.

[Q: 3817] OnExamination 2012 - Psychiatry

Which of the following is true regarding depersonalisation syndrome?

- 1- Characteristically precedes derealisation
- 2- Is a feeling that other people have changed
- 3- Is an indication for electroconvulsive therapy (ECT)
- 4- Is associated with depression
- 5- Precedes the onset of schizophrenia

Answer & Comments

Answer: 4- Is associated with depression

Depersonalisation is not exclusively seen in schizophrenics.

The feeling that other people have changed is derealisation - see below.

Depersonalisation may occur in

- Almost all major psychiatric disorders
- Drug abuse
- Migraine
- Epilepsy
- Systemic lupus erythematosus (SLE)

and, transiently, in

Normal individuals.

ECT has been tried in the past.

Selective serotonin reuptake inhibitor (SSRI) antidepressants and coping strategies are useful.

Derealisation is a separate pathology.

Depersonalisation is a change in an individual's self-awareness such that they feel detached from their own experience with the self, the body and mind seeming alien.

Derealisation is a change in an individual's experience of the environment where the world around them feels unreal and unfamiliar.

[Q: 3818] OnExamination 2012 - Psychiatry

A 30-year-old male presented with a paranoid psychosis accompanied by visual hallucinations which resolved over the next three days.

Which one of the following is the most likely diagnosis?

- 1- Alcohol withdrawal.
- 2- Diazepam dependence.
- 3- Fluoxetine overdose.
- 4- Heroin withdrawal.
- 5- Smoking cannabis.

Answer & Comments

Answer: 1- Alcohol withdrawal.

The key points in the history are that, firstly, these are visual hallucinations and secondly that they resolve over 72 hours. Of all the options given, alcohol withdrawal is the most likely. The fact that this patient has paranoid psychosis makes it even more likely.

Symptoms typically present about 8 hours after a significant fall in blood alcohol levels. The peak is on day two, and by day five the symptoms are significantly better. Minor withdrawal symptoms appear 6-12 hours after cessation of alcohol and include: insomnia, fatigue, tremor, anxiety, nausea, vomiting, headache, sweating, palpitations, anorexia, depression and craving. Alcoholic hallucinosis can appear 12-24 hours after stopping alcohol and includes visual, auditory

and tactile hallucinations. Withdrawal seizures can appear 24-28 hours after cessation and are generalised tonic-clonic seizures. Alcohol withdrawal delirium ('delerium tremens') can appear 48-72 hours after cessation. Mortality without treatment is approximately 35%.

Benzodiazepines can cause a protracted withdrawal syndrome, with symptoms persisting for 6 months or more. It is characterised by anxiety, irritability, insomnia and sensory disturbance. In severe cases it can resemble mania and schizophrenia.

Fluoxetine overdose typically causes few symptoms, but can be associated with arrhythmias.

Heroin withdrawal has significant physical symptoms, including tremors, cramps, muscle and bone pain, rhinitis, tachycardia and diarrhoea and vomiting, in addition to psychiatric symptoms.

Cannabis use causes relaxation, euphoria, short-term memory loss and dry mouth and eyes. A withdrawal syndrome is recognised but not well defined. Long-term use has been linked with paranoia and schizophrenia, but these symptoms do not resolve quickly and visual hallucinations are unlikely.

[Q: 3819] OnExamination 2012 - Psychiatry

A student is worried that she may not be able to take her final university examinations in three months time because she says she becomes faint and dizzy when she does examinations.

What is the most appropriate course of action?

- 1- 24 hour ECG monitoring
- 2- Advise her to withdraw from examinations on medical grounds
- 3- Arrange counselling, with relaxation training

4- Prescribe diazepam

5- Prescribe fluoxetine

Answer & Comments

Answer: 3- Arrange counselling, with relaxation training

The symptoms the student describes are characteristic of stress/anxiety and are quite common.

She should be reassured.

Electrocardiogram (ECG) monitoring would support her fears of organic disease.

Diazepam would impair her examination performance and fluoxetine may increase feelings of anxiety.

[Q: 3820] OnExamination 2012 - Psychiatry

A 22-year-old woman complains of haemoptysis, abdominal pains and pyrexia for a month.

She is admitted to hospital and found to be afebrile and haemodynamically stable. There are numerous crusted, linear lesions on her forearms.

What is the most likely diagnosis?

- 1- Acute intermittent porphyria
- 2- Factitious disorder
- 3- Systemic lupus erythematosus
- 4- TB
- 5- Wegener's granulomatosis

Answer & Comments

Answer: 2- Factitious disorder

The history is very vague and the patient has no clinical features other than a rash which sounds typical of dermatitis artefacta.

The crusted lesions on the forearms suggest artefacta or wounds from recent self harm as this is the most typical site for these lesions.

Porphyria may be expected to have vesicles on sun exposed regions, face, arms and legs.

[Q: 3821] OnExamination 2012 - Psychiatry

Which of the following is true of obsessional neurosis (obsessive compulsive disorder)?

- 1- Low intelligence is a common feature
- 2- Patients have good insight
- 3- Patients often act on their aggressive impulses
- 4- The onset is usually after the age of 50 years
- 5- There is often a history of faulty toilet training

Answer & Comments

Answer: 2- Patients have good insight

Obsessional neurosis is associated with rituals, fears (for example, hurting others but never carried out), thoughts abhorrent to the patient and ruminations.

The illness is distressing to them and may cause depression.

It usually starts in early adult life with equal sex incidence.

The intelligence of these subjects is often above average.

[Q: 3822] OnExamination 2012 - Psychiatry

Which of the following symptoms is more suggestive of a functional disorder?

- 1- Disorientation in time
- 2- Inability to retain new information
- 3- Mutism

4- Perseveration

5- Visual hallucinations

Answer & Comments

Answer: 3- Mutism

Functional refers to an illness that is without a structural defect.

Organic brain syndromes are physical conditions including structural brain disease and metabolic disturbances causing mental dysfunction.

Mutism is the most likely of the symptoms described to be associated with a functional disorder but is associated with schizophrenia or autism.

[Q: 3823] OnExamination 2012 - Psychiatry

A 17-year-old student presented with recurrent attacks of dizziness.

Which one of the following additional features is most suggestive that she has an anxiety disorder?

- 1- Elevated diastolic blood pressure
- 2- Nocturia
- 3- Paraesthesia in the hands
- 4- Rotational vertigo
- 5- Tinnitus

Answer & Comments

Answer: 3- Paraesthesia in the hands

Paraesthesia is often experienced with hyperventilation associated with anxiety disorders and is often in hands, feet and periorally.

Rotational vertigo and tinnitus suggest an organic disorder, whilst anxiety disorder may be associated with raised systolic blood pressure, but not diastolic

[Q: 3824] OnExamination 2012 - Psychiatry

An 18-year-old female is reluctant to eat food that is prepared for her.

Which one of the following would be most consistent with a diagnosis of anorexia nervosa?

- 1- She believes the food is poisoned
- 2- She has a full-time job
- 3- She has bouts of heavy drinking
- 4- She regards herself as ill
- 5- She secretly abuses anabolic steroids

Answer & Comments

Answer: 2- She has a full-time job

Anorexia nervosa is associated with the abnormal perception of body image.

Patients generally feel well despite the protestations of others who think that they look awful. They exercise avidly and until the very late stages of the disease hold down full time jobs.

There is no delusion with regard to the food being poisoned.

Heavy drinking associated with food refusal would suggest alcoholism and alcoholic gastritis.

The secretive abuse of laxatives would fit with the diagnosis rather than anabolic agents.

[Q: 3825] OnExamination 2012 - Psychiatry

A 25-year-old male with learning difficulties presents with behavioural problems.

He confessed to smoking the occasional cannabis joint.

Which of the following is most likely to be the cause of his behavioural problems?

- 1- Cannabis

- 2- Dementia
- 3- Depression
- 4- Mania
- 5- Schizophrenia

Answer & Comments

Answer: 3- Depression

This man may be frustrated by his incapacity and would appear to be having behavioural problems as a manifestation of his depression.

Cannabis may actually relieve these frustrations.

There are no features to suggest an organic brain syndrome.

[Q: 3826] OnExamination 2012 - Psychiatry

An 18-year-old man had repeated episodes of breathlessness and palpitations, lasting about 20 minutes and resolving gradually.

There were no abnormal physical signs.

What is the most likely cause of these features?

- 1- Drug abuse
- 2- Panic disorder
- 3- Paroxysmal supraventricular tachycardia (SVT)
- 4- Personality disorder
- 5- Thyrotoxicosis

Answer & Comments

Answer: 2- Panic disorder

Drug abuse is unlikely since the symptoms are quite short lived.

We would expect other symptoms such as gastrointestinal (GI) disturbance, headaches or hypertension to accompany a variety of drug abuse causes.

Paroxysmal SVT would start and stop suddenly, not gradually.

Personality disorder and thyrotoxicosis would both be expected to lead to symptoms of longer duration with other associated symptoms.

This leaves 'panic disorder' as the most likely diagnosis.

[Q: 3827] OnExamination 2012 -
Ophthalmology

Which of the following conditions is associated with a pathognomonic retinal change?

- 1- Infective endocarditis
- 2- Polycythaemia rubra vera
- 3- Sickle cell anaemia
- 4- Toxoplasmosis
- 5- Wilson's disease

Answer & Comments

Answer: 3- Sickle cell anaemia

Sickle cell disease (SCD) is associated with the 'black sunburst' - a chorioretinal scar, which is one of the commoner retinal manifestations of SCD and pathognomonic.

Roth spots, seen in infective endocarditis, are also seen in leukaemia.

Choroidoretinitis in toxoplasmosis may also be seen with other disorders.

The Kayser-Fleischer (KF) rings of Wilson's disease are found on the iris.

[Q: 3828] OnExamination 2012 -
Ophthalmology

A 50-year-old man presented with a three day history of floaters and blurred vision in his left eye.

What is the diagnosis?

- 1- Angioid streaks
- 2- Arteriolar embolus
- 3- Diabetic retinopathy
- 4- Macular degeneration
- 5- Reactivation of Toxoplasma chorioretinitis

Answer & Comments

Answer: 5- Reactivation of Toxoplasma chorioretinitis

Toxoplasma chorioretinitis is the most common cause of infectious retinitis in immunocompetent individuals. It is caused by the obligate intracellular protozoan parasite *Toxoplasma gondii*, the definitive host of which is the cat. Human infection occurs following ingestion of cysts, which are shed in cat faeces, via contaminated drinking water or infected meat.

Reactivation may occur following infection and is commonly seen as an area of inflammation adjacent to an area of chorioretinal scarring.

The photograph shows a colour photograph of the left fundus with a white area of inflammation adjacent to a scar nasal to the optic disc.

There may be coexisting vitritis and aqueous cells and keratic precipitates. Diagnosis is confirmed by serology. Patients should be referred to a specialist ophthalmic unit for treatment.

Regarding the listed options:

A. Angioid streaks is incorrect. These are dark linear lesions with irregular edges, radiating out from the optic disc. They are caused by breaks in Bruch's membrane and are associated with systemic diseases including

- Pseudoxanthoma elasticum
- Ehlers-Danlos syndrome
- Paget's disease
- Thalassaemias.

B. Arteriolar embolus is incorrect. This would cause retinal pallor distal to the location of the embolus.

C. Diabetic retinopathy is incorrect as there are no signs of diabetic retinopathy (for

example, haemorrhage, exudates, cotton wool spots).

D. Macular degeneration is incorrect as the macula is healthy.

E. Reactivation of Toxoplasma chorioretinitis is correct.

[Q: 3829] OnExamination 2012 - Ophthalmology

A 45-year-old woman presents with a three day history of red right eye associated with an aching pain. She reports the pain is so severe it keeps her awake at night. Her vision is unaffected.

Photo of her right eye shows vasodilation of the deep and superficial episcleral vessels, which did not blanch on application of topical phenylephrine 2.5%. Her globe was tender and she experienced pain on eye movements.

Her past medical history includes Crohn's disease.

What is the diagnosis?

- 1- Acute anterior uveitis
- 2- Blepharoconjunctivitis
- 3- Conjunctivitis
- 4- Episcleritis
- 5- Scleritis

Answer & Comments

Answer: 5- Scleritis

Scleritis is a rare cause of red eye, associated with severe aching pain which classically disturbs sleep. The pain may be worse on eye movements and the eye is tender to touch.

It is associated with systemic diseases including:

Rheumatoid arthritis

Wegener's granulomatosis

Polyarteritis nodosa

Systemic lupus erythematosus

Sarcoidosis

Inflammatory bowel disease.

Episcleritis is a common cause of red eye which may be associated with mild discomfort. Application of topical phenylephrine 2.5% leads to blanching of episcleral vessels in episcleritis but not in scleritis.

A. Acute anterior uveitis is incorrect as it does not cause sectoral redness.

B. Blepharoconjunctivitis is incorrect as it does not cause severe pain or pain on eye movements.

C. Conjunctivitis is incorrect as above.

D. Episcleritis is incorrect as it does not lead to severe pain associated with disturbing sleep. Topical phenylephrine 2.5% leads to blanching of vessels in episcleritis.

E. Scleritis is correct.

[Q: 3830] OnExamination 2012 - Ophthalmology

A 53-year-old woman presents with a five day history of a painful left eye.

On examination there is a small white infiltrate on the inferior aspect of her left cornea, which is close to the limbal edge, but separated from it by an area of clear cornea.

The infiltrate stains with fluorescein and there is significant blepharitis affecting both lid margins. She reports no contact lens wear.

Her past medical history includes rheumatoid arthritis.

What is the diagnosis?

- 1- Anterior uveitis
- 2- Corneal abrasion
- 3- Herpes simplex keratitis
- 4- Hypopyon

5- Marginal keratitis

Answer & Comments

Answer: 5- Marginal keratitis

A. Anterior uveitis is incorrect as this does not cause an infiltrate.

B. Corneal abrasion is incorrect as there is an infiltrate present indicating keratitis.

C. Herpes simplex keratitis is incorrect.

D. Hypopyon is incorrect, this refers to a collection of inflammatory material in the anterior chamber resulting in an opaque fluid level visible inferiorly. It occurs in severe cases of anterior uveitis or endophthalmitis.

E. Marginal keratitis is correct.

Marginal keratitis is areas of peripheral corneal infiltrates/ulcers associated with blepharitis. It classically causes an infiltrate near the limbal edge with an area of clear cornea. There may be limbal vessels growing towards the lesion/s.

It is thought to be caused by a hypersensitivity reaction to staphylococcal exotoxins from *Staphylococcus aureus* present on the lid margins in blepharitis.

Treatment involves topical steroids for the keratitis and lid hygiene advice and topical antibiotics to treat the underlying blepharitis. In severe cases oral doxycycline can also be used.

[Q: 3831] OnExamination 2012 - Ophthalmology

A 50-year-old man presented with a three day history of red eye associated with pain, blurring of vision and photophobia.

Examination revealed cells in the anterior chamber. He was diagnosed with anterior uveitis. A photo of his eye is shown with a characteristic sign of anterior uveitis.

What is the diagnosis?

1- Corneal oedema

2- Hypopyon

3- Keratic precipitates

4- Posterior synechiae

5- Punctuate epithelial erosions

Answer & Comments

Answer: 3- Keratic precipitates

Of the listed options,

Option:

A. Corneal oedema is incorrect as the cornea is clear allowing visualisation of the iris details.

B. Hypopyon is incorrect. This is a collection of inflammatory exudate in the anterior chamber resulting in a white fluid level. It is associated with severe inflammation in the eye.

C. Keratic precipitates is correct. The photograph shows small opaque aggregates on the endothelium.

D. Posterior synechiae is incorrect, the pupil is dilated, spherical and symmetrical.

E. Punctuate epithelial erosions is incorrect. They are fine defects of the epithelium which show up with fluorescein. They are not a sign of anterior uveitis.

[Q: 3832] OnExamination 2012 - Ophthalmology

A 47-year-old man, who is currently being treated with quadruple therapy for pulmonary tuberculosis comes to the Emergency department complaining of a sudden deterioration in the visual acuity in his left eye and loss of colour vision.

Which of the following anti-tuberculous agents is most likely to have been responsible?

1- Ethambutol

- 2- Isoniazid
- 3- Pyrazinamide
- 4- Rifampicin
- 5- Streptomycin

Answer & Comments

Answer: 1- Ethambutol

The answer is ethambutol, which is associated with:

Retrobulbar neuritis

Generalised cutaneous reactions

Hepatitis

Peripheral neuropathy.

The retrobulbar neuritis seen with ethambutol may be unilateral or bilateral; as such unilateral symptoms do not preclude the diagnosis.

Isoniazid is associated with peripheral neuropathy, skin rash and hepatitis

Pyrazinamide can cause arthralgia and hepatitis.

Streptomycin is associated with vestibular and auditory nerve damage.

Rifampicin causes orange discolouration of secretions, and may cause hepatitis.

[Q: 3833] OnExamination 2012 - Ophthalmology

A 47-year-old man, otherwise fit and healthy, complained of a one week history of not being able to see objects placed at the centre of his visual fields, even with both eyes opened.

An objective visual fields test revealed an incongruous binasal hemianopia.

What is the most likely diagnosis?

- 1- Carotid-cavernous sinus fistula
- 2- Craniopharyngioma

- 3- External carotid artery dissection
- 4- Internal carotid artery displacement
- 5- Pituitary tumour

Answer & Comments

Answer: 4- Internal carotid artery displacement

Bilateral internal carotid artery displacement can cause binasal incongruous hemianopia if the optic nerves are compressed.

[Q: 3834] OnExamination 2012 - Ophthalmology

Which one of the following diseases is most likely to be associated with scleritis?

- 1- Ankylosing spondylitis
- 2- Crohn's disease
- 3- Rheumatoid arthritis
- 4- SLE
- 5- Ulcerative colitis

Answer & Comments

Answer: 3- Rheumatoid arthritis

Rheumatoid arthritis is associated with scleritis, whereas the other choices are more associated with anterior uveitis.

[Q: 3835] OnExamination 2012 - Ophthalmology

A 26-year-old tall, thin, lady with a known cardiac valvulopathy, was reported to have skin laxity and folds on the back of the neck and her underarms.

Fundoscopy revealed bilateral angioid streaks with optic disc drusens.

What is the most likely diagnosis?

- 1- Ehlers-Danlos syndrome
- 2- Marfan's syndrome
- 3- Menkes syndrome

- 4- Osteogenesis imperfecta
5- Pseudoxanthoma elasticum

Answer & Comments

Answer: 5- Pseudoxanthoma elasticum

Pseudoxanthoma elasticum with angioid streaks is also known as Grönblad-Strandberg syndrome.

Ehlers-Danlos and Marfan's syndrome are not associated with laxity and folds of skin on the back of the neck.

Menkes syndrome and osteogenesis imperfecta are not associated with angioid streaks.

[Q: 3836] OnExamination 2012 - Ophthalmology

A 28-year-old Lebanese lady developed left branch retinal artery occlusion (BRAO) one week after an uneventful elective caesarean section. She also developed some mouth and vulval ulcers two weeks post-partum.

Visual acuity in the affected left eye was counting fingers.

Full blood picture, U&Es and coagulation screen were all within normal limits. CRP was 28. Anti-nuclear antibody, ANA titre was 1:20.

What is the most likely cause of her left BRAO?

- 1- Amniotic fluid embolus
2- Behçet's disease
3- Fat embolus
4- Reiter's syndrome
5- SLE

Answer & Comments

Answer: 2- Behçet's disease

This lady with thrombosis and oro-genital ulceration has Behçet's syndrome.

Behçet's syndrome is a systemic vasculitis with an unknown aetiology, which affects small and large vessels (venous and arterial). More than 60% of patients are HLA-B51, and there is an increased prevalence in the Mediterranean countries. It is commonly associated with mucocutaneous manifestations (oro-genital ulceration, erythema nodosum), ocular disease, gastrointestinal involvement and neurological features. Venous thrombosis is a common complication, but arterial occlusion can also occur.

The International Study Group criteria for classification of Behçet's disease requires the presence of recurrent oral ulceration (minor aphthous, major aphthous or herpetiform ulceration observed by physician or patient, which have recurred at least three times in a 12 month period), and two of the following:

- Recurrent genital ulceration: aphthous ulceration or scarring, observed by physician or patient
- Eye lesions: anterior uveitis, posterior uveitis, or cells in vitreous on slit lamp examination; or retinal vasculitis observed by ophthalmologist
- Skin lesions: erythema nodosum observed by physician or patient, pseudofolliculitis or papulopustular lesions; or acneiform nodules observed by the physician in post-adolescent patients not on corticosteroid treatment
- Positive pathergy test: read by physician at 24-48 hours.

Pathergy is the non-specific hyper-reactivity of the skin following minor trauma, and is specific to Behçet's disease. It involves intradermal injection of skin with a 20-gauge needle under sterile conditions. It is considered positive if an erythematous sterile papule develops within 48 hours.

Recurrent oral ulcers occur in SLE but genital ulcers are less common. Additional features are usually present in this condition.

Reiter's syndrome (reactive arthritis) is not typically associated with thrombosis.

Amniotic fluid embolism presents with rapid cardiovascular collapse, acute left ventricular failure with pulmonary oedema, disseminated intravascular coagulation and neurological impairment.

Fat embolism usually presents following long bone fracture, and causes an acute respiratory distress syndrome associated with fever, petechial rash and neurological impairment.

[Q: 3837] OnExamination 2012 - Ophthalmology

A 64-year-old man presents with redness affecting his right eye, having noticed it on waking two days earlier.

He reports no pain, watering or discharge and his vision is unaffected. There was no corneal staining with fluorescein.

What is the diagnosis?

- 1- Conjunctivitis
- 2- Episcleritis
- 3- Herpes simplex keratitis
- 4- Iritis
- 5- Subconjunctival haemorrhage

Answer & Comments

Answer: 5- Subconjunctival haemorrhage

A. Conjunctivitis is incorrect as it causes diffuse redness associated with discharge.

B. Episcleritis is incorrect as although it can cause sectoral redness the conjunctival vessels are still visible.

C. Herpes simplex keratitis is incorrect. This is a cause of painful red eye and classically a

dendritic ulcer visible with fluorescein staining.

D. Iritis is incorrect as it is a cause of painful red eye, associated with watering, photophobia and blurring of vision.

[Q: 3838] OnExamination 2012 - Ophthalmology

Which of the following may be associated with optic atrophy (OA)?

- 1- Anti-acetylcholinesterase antibodies
- 2- Intense iron deposition on liver biopsy
- 3- Low plasma caeruloplasmin
- 4- Red ragged fibres on muscle biopsy
- 5- XXY karyotype

Answer & Comments

Answer: 4- Red ragged fibres on muscle biopsy

Red ragged fibres found in mitochondrial myopathy are found in Kearns-Sayre syndrome; mitochondrial myopathy, lactic acidosis and stroke-like episodes (MELAS); and Leber's optic atrophy.

Wilson's disease is associated with Kayser-Fleischer (KF) rings; and myotonic dystrophy rather than myasthenia gravis is associated with OA.

OA is not associated with Klinefelter's disease.

[Q: 3839] OnExamination 2012 - Ophthalmology

A 31-year-old man presented with raised yellow lesions above the left upper eye lid.

What is the diagnosis?

- 1- Acne rosacea
- 2- Eczema
- 3- Herpes simplex

4- Herpes zoster ophthalmicus

5- Molluscum contagiosum

Answer & Comments

Answer: 3- Herpes simplex

Herpes simplex virus may lie dormant in the trigeminal ganglion, reactivation can occur giving rise to eyelid and periorbital vesicles. The patient may experience prodromal facial and lid tingling, and may have associated conjunctivitis, lid swelling and/or keratitis.

It can be treated with topical or oral aciclovir (for example, 400 mg five times a day for three days¹) although oral aciclovir is usually better tolerated.

In patients with atopic dermatitis or eczema herpes simplex infection can cause eczema herpeticum, which may be further complicated by secondary staphylococcal infection. This is treated by adding oral antibiotics, for example, flucloxacillin 500 mg q.i.d.

Eczema herpeticum is a serious and potentially life-threatening condition which may require medical and dermatology input.

[BNF treatment for non-genital herpes simplex treatment is aciclovir 200 mg (400 mg in the immunocompromised or if absorption impaired) five times daily usually for five days (longer if new lesions appear during treatment or if healing incomplete).]

A. Acne rosacea is incorrect. This causes facial erythema commonly affecting the cheeks, nose and forehead.

B. Eczema is incorrect. This is a form of dermatitis characterised by dryness and erythema. Herpes simplex in atopic individuals can give rise to eczema herpeticum which is treated with both systemic antivirals and antibiotics.

C. Herpes simplex is correct.

D. Herpes zoster ophthalmicus is caused by the varicella zoster virus, which starts as a maculopapular rash progressing to vesicles, pustules and crusting in the distribution of the dermatome served by the ophthalmic division of the trigeminal nerve. It mainly affects elderly patients but may affect younger patients and is more severe in patients who are immunocompromised.

E. Molluscum contagiosum is incorrect, this is also caused by a viral infection (human specific double-stranded DNA poxvirus) but gives rise to pearly umbilicated lesions. It commonly affects children, most commonly between the ages of 2 and 4.

It is highly contagious and is transmitted by contact. Treatment may not be necessary unless the lesions are close to the lid margin, in which case treatment options include shave excision or cauterisation.

Reference:

Kanski JJ. Clinical Ophthalmology: A systematic approach. 6th edition, Butterworth-Heinemann, 2007.

[Q: 3840] OnExamination 2012 - Ophthalmology

A 24-year-old wearer of daily disposable contact lenses presented with a two day history of red eye with associated soreness.

Examination revealed a small corneal ulcer on her right eye.

What would be first line treatment?

- 1- Brolene drops two hourly
- 2- Chloramphenicol drops four times a day
- 3- Fucithalamic ointment twice a day
- 4- Levofloxacin hourly
- 5- Predsol drops four times a day

Answer & Comments

Answer: 4- Levofloxacin hourly

A. Brolene is incorrect as it does not treat *Pseudomonas aeruginosa* which is commonly associated with contact lens related infections.

It is used in the management of Acanthamoeba keratitis, which is a rare and serious keratitis associated with contact lens (CL) wear. Risk factors for Acanthamoeba keratitis are exposure of CL to contaminated water, for example, using tap water to clean CL or swimming in lenses.

Clinical features of Acanthamoeba keratitis include pain out of proportion to clinical signs, ring infiltrates and radial keratoneuritis.

B. Chloramphenicol is incorrect as above as it does not cover *Pseudomonas*.

C. Fucithalmic is incorrect as above.

D. Levofloxacin hourly is correct. The management must also include advising the patient to discontinue wearing contact lenses and referral to a specialist ophthalmic unit.

E. Predsol is incorrect and contraindicated as sole therapy in the management of contact lens related keratitis.

[Q: 3841] OnExamination 2012 - Ophthalmology

A 28-year-old man presents with a three day history of 'gritty pain' in his right eye with pain on blinking. He recollects no history of trauma.

He is otherwise well but occasionally experiences cold sores.

On examination there are multiple linear epithelial defects.

Which of the options below must be included in the management?

- 1- Aciclovir ointment
- 2- Everting the eyelid
- 3- Oral antibiotics

4- Orbital x ray

5- Topical steroid drops

Answer & Comments

Answer: 2- Everting the eyelid

Options A, C, D and E are incorrect as they would fail to solve the cause of the problem.

Option B, everting the eyelid, is the correct answer as symptoms and signs are suggestive of a subtarsal foreign body so the appropriate management would be to examine underneath the lid to search for and remove a foreign body.

Further management would involve topical chloramphenicol ointment three to four times a day for five days.

[Q: 3842] OnExamination 2012 - Ophthalmology

A 33-year-old man presents with a four day history of painful loss of vision. His past medical history includes eczema and hay fever.

On examination his cornea is opaque and appears to be protruding. The corneal surface appears irregular but there is no staining with fluorescein.

What is the diagnosis?

- 1- Acute anterior uveitis
- 2- Acute corneal hydrops
- 3- Episcleritis
- 4- Herpes simplex keratitis
- 5- Scleritis

Answer & Comments

Answer: 2- Acute corneal hydrops

Acute corneal hydrops occurs in advanced keratoconus, which is the most common cause of corneal ectasia.

The cornea is made of 3 main layers:

Epithelium

Stroma

Endothelium

The transparency of the cornea is maintained by the endothelium which constantly pumps water out from the stroma.

Descemet's membrane is a specialised basement membrane which lies between the endothelium and stroma, which helps to provide structural integrity to the cornea. In acute corneal hydrops the endothelium and Descemet's membrane split which allows aqueous to enter the corneal stroma.

Stromal and epithelial oedema results in corneal opacification and formation of epithelial bullae.

Keratoconus is associated with atopic conditions (for example, asthma, hay fever, eczema) and Down's syndrome.

Options A, C, D and E are incorrect as they do not cause this level of corneal oedema or protrusion of the cornea.

Acute corneal hydrops (option B) is correct as it results in acute blurring of vision associated with corneal opacification and corneal protrusion.

[Q: 3843] OnExamination 2012 - Ophthalmology

An 18-year-old man was found to have multiple small pigmented lesions in the peripheral retina of both eyes.

These lesions resembled bear tracks. However, his visual acuity was 6/6 on the Snellen chart in both eyes. His father also had similar lesions.

Which one of the following would be the best next step in managing this man's condition?

1- Referral to cardiology

2- Referral to endocrinology

3- Referral to gastroenterology

4- Referral to infectious disease specialist

5- Referral to ophthalmology

Answer & Comments

Answer: 3- Referral to gastroenterology

This description of the lesion is that of congenital hypertrophy of retinal pigment epithelium (CHRPE), which is associated with autosomal dominantly inherited familial adenomatous polyposis (FAP).

A referral to gastroenterology is the best next step.

[Q: 3844] OnExamination 2012 - Ophthalmology

A 45-year-old lady with rheumatoid arthritis attended a routine appointment at the rheumatology clinic, and was complaining of a two day history of right red eye with dull pain.

She denied any photophobia and there was no ocular discharge noted.

What is the most likely diagnosis?

1- Acute angle closure glaucoma

2- Conjunctivitis

3- Inflammation caused by corneal melt

4- Scleritis

5- Scleromalacia perforans

Answer & Comments

Answer: 4- Scleritis

Rheumatoid arthritis is associated with both scleritis and episcleritis.

Scleritis may cause severe pain and results in diffuse or nodular injection.

Episcleritis results in ocular irritation with nodules.

In the absence of photophobia and discharge, scleritis would be the best answer.

[Q: 3845] OnExamination 2012 - Ophthalmology

A 34-year-old man, who has just recovered from gastroenteritis following a recent trip to Turkey, suddenly developed progressive gait ataxia and restriction of eye movements in all directions of gaze.

There was no nystagmus.

What is the most likely diagnosis?

- 1- Acute cerebellar degeneration
- 2- Millard-Gubler syndrome
- 3- Miller-Fisher syndrome
- 4- Parinaud's syndrome
- 5- Subacute combined degeneration of the spinal cord

Answer & Comments

Answer: 3- Miller-Fisher syndrome

Miller-Fisher syndrome is a variant/spectrum of Guillain-Barré syndrome (GBS).

GBS is associated with Campylobacter jejuni infection, which can trigger this syndrome.

Miller-Fisher is classically described as a triad of:

- * External ophthalmoplegia
- * Ataxia
- * Areflexia

so the above history would be most in keeping with Miller-Fisher syndrome.

[Q: 3846] OnExamination 2012 - Ophthalmology

A 61-year-old emmetropic female nurse presented with a three day history of missing steps when walking down the stairs as she was seeing double of each of the steps. She

reported no such problems when walking up the stairs.

She admitted to bumping her head moderately hard when trying to get out of her car four days ago. She denied any deterioration of her visual acuity.

No horizontal diplopia was elicited.

What is the most likely cause of her problems?

- 1- Right inferior oblique palsy
- 2- Right inferior rectus palsy
- 3- Right superior oblique palsy
- 4- Right superior rectus palsy
- 5- This patient needs glasses for distance

Answer & Comments

Answer: 3- Right superior oblique palsy

This patient essentially suffered from vertical diplopia following bumping her head moderately hard.

The fourth cranial nerve can be affected in such a situation resulting in superior oblique palsy.

[Q: 3847] OnExamination 2012 - Ophthalmology

A 60-year-old man presents with an acute red eye.

Of the following conditions which is the most likely cause?

- 1- Closed angle glaucoma
- 2- Optic neuritis
- 3- Retinal vein occlusion
- 4- Retinal detachment
- 5- Vitreous haemorrhage

Answer & Comments

Answer: 1- Closed angle glaucoma

Of those listed the most likely to present with an acute red eye would be glaucoma.

Other causes of acute red eye include

Anterior uveitis

Corneal ulcers

Conjunctivitis

Scleritis

Episcleritis

Subconjunctival haemorrhage.

Optic neuritis presents with a particular type of central visual loss - a central scotoma.

Retinal vein occlusion, retinal detachment and vitreous haemorrhage would present as visual loss or disturbance.

[Q: 3848] OnExamination 2012 - Ophthalmology

A 34-year-old man presented with a two day history of red eye, associated with sharp pain, watering, photophobia and blurring of vision. He does not wear contact lenses.

He reports having two similar episodes over the past two years.

Examination revealed reduced corneal sensation and an irregular epithelial defect.

What is the diagnosis?

- 1- Episcleritis
- 2- Herpes simplex keratitis
- 3- Marginal keratitis
- 4- Microbial keratitis
- 5- Recurrent corneal erosion syndrome

Answer & Comments

Answer: 2- Herpes simplex keratitis

A. Episcleritis is incorrect as it does not cause a dendritic ulcer or reduced corneal sensation.

B. Herpes simplex keratitis is correct.

C. Marginal keratitis is incorrect as this causes ulceration close to the limbus, is neither dendritic in appearance nor causes reduced corneal sensation.

D. Microbial keratitis is incorrect as this does not cause a dendritic ulcer but usually a more spherical ulcer with associated infiltrate.

E. Recurrent corneal erosion syndrome is incorrect as this does not cause a dendritic ulcer or reduced corneal sensation. It is associated with previous corneal abrasions and classically presents with sudden onset severe pain typically occurring in the early hours of the morning.

[Q: 3849] OnExamination 2012 - Ophthalmology

A patient presents with deteriorating vision.

On examination, fundoscopy reveals retinitis pigmentosa.

Which of the following conditions would be unlikely to be responsible for this presentation?

- 1- Abetalipoproteinaemia
- 2- Friedreich's ataxia
- 3- Kearns-Sayre syndrome
- 4- Laurence-Moon-Biedl syndrome
- 5- Refsum's disease

Answer & Comments

Answer: 2- Friedreich's ataxia

Causes of pigmentary retinopathy include Usher's syndrome and mitochondrial myopathy.

Abetalipoproteinaemia is autosomal recessive and is associated with:

Hypocholesterolaemia syndrome resembling Friedreich's ataxia

Abnormally shaped red blood cells (RBC)
(acanthocytes)

Steatorrhoea and

Fatty liver.

Friedreich's is associated with optic atrophy.

[Q: 3850] OnExamination 2012 -
Ophthalmology

This is the appearance of the eye of a 32-year-old man who presents with blurring of vision.

Which of the following conditions would give rise to this appearance?

- 1- Cushing's syndrome
- 2- Diabetes mellitus
- 3- Hypertension
- 4- Marfan's syndrome
- 5- Reactive arthritis

Answer & Comments

Answer: 4- Marfan's syndrome

The image shows ectopia lentis with inferior dislocation of the crystalline lens.

Ectopia lentis is typically seen in connective tissue disorders such as

Marfan's syndrome

Ehlers-Danlos

Homocystinuria

Weill-Marchesani and

Osteogenesis imperfecta.

It can also be seen following trauma or surgery.

In Marfan's syndrome, lens dislocation often occurs supero-temporally, but not invariably.

[Q: 3851] OnExamination 2012 -
Ophthalmology

A 37-year-old homosexual male presented to the medical take with an acute onset of reduced vision in his left eye.

Fundoscopy of the left eye revealed an extensive 'brushfire-like' lesion in the major superior temporal arcade with a large patch of white fluffy lesion mixed with extensive retinal haemorrhages.

What is the most likely diagnosis?

- 1- CMV retinitis
- 2- Ocular histoplasmosis
- 3- Syphilitic choroiditis
- 4- Syphilitic neuroretinitis
- 5- Tuberculous periphlebitis

Answer & Comments

Answer: 1- CMV retinitis

This is a classic example of Cytomegalovirus (CMV) retinitis secondary to human immunodeficiency virus (HIV), as is suggestive of the information given in this scenario.

Ocular histoplasmosis and syphilitic choroiditis would give a fundus picture of multiple whitish lesions.

Syphilitic neuroretinitis would normally give a picture of a macular star exudation.

Tuberculous periphlebitis is the next closest answer, but does not fit the description of 'brushfire-like' lesion in that it gives a picture of perivenous sheathing and minimal retinal haemorrhages.

[Q: 3852] OnExamination 2012 -
Ophthalmology

A 65-year-old hypermetropic lady was seen in an acute unselected medical take.

She presented with a three hour history of dull pain, lacrimation, photophobia and reduced vision in the right eye.

She had no significant past medical history.

Ocular examination revealed a painful red eye with an oval shaped pupil.

What is the most likely diagnosis?

- 1- Acute angle closure glaucoma
- 2- Episcleritis
- 3- Iritis
- 4- Keratoconjunctivitis
- 5- Scleritis

Answer & Comments

Answer: 1- Acute angle closure glaucoma

Red eye of an acute painful dull nature, with photophobia and reduced vision in a hypermetropic person is highly indicative of acute angle closure glaucoma.

The pupil in this condition is usually mid-dilated oval shaped.

The oval shape is due to the iris sphincter ischaemia from the high intraocular pressure.

[Q: 3853] OnExamination 2012 - Ophthalmology

A 75-year-old man developed a gradual problem of not being able to look down over the last eight months. Then about two months ago, he was also not able to look up. He denied any diplopia, ocular pain or headaches.

There was no evidence of convergence retraction nystagmus, proptosis or ptosis.

What is the most likely diagnosis?

- 1- Chronic progressive external ophthalmoplegia
- 2- Ocular myasthenia
- 3- Ocular myositis

4- Parinaud's syndrome

5- Thyroid eye disease

Answer & Comments

Answer: 1- Chronic progressive external ophthalmoplegia

The history itself suggests a chronic progressive limitation of eye movements without any diplopia, proptosis or ptosis. Therefore, the most likely diagnosis is chronic progressive external ophthalmoplegia.

Ocular myasthenia usually presents with diplopia and ptosis.

Parinaud's syndrome usually manifests as up gaze palsy with convergence retraction nystagmus.

[Q: 3854] OnExamination 2012 - Ophthalmology

A 24-year-old lady with a BMI of 36 and on the combined oral contraceptive pill presented with a one month history of increasing vertex headaches, worse in the mornings and worse on coughing and sneezing. She also complained of blurry vision in both eyes.

Fundoscopy revealed bilateral extensive papilloedema with a lot of flame shaped haemorrhages around and on the optic discs.

Which one of the following is the best long term management of this patient?

- 1- Changing the combined oral contraceptive pill to an oestrogen based one
- 2- Commence on aspirin
- 3- Perform lumbar puncture
- 4- Reduce weight
- 5- Start oral acetazolamide

Answer & Comments

Answer: 4- Reduce weight

This patient has idiopathic intracranial hypertension. The best long term management is weight reduction, which can improve her symptoms.

Changing the combined oral contraceptive pill to a more oestrogen based one can worsen the symptoms.

Lumbar puncture and acetazolamide can help improve the symptoms, but should not be considered as long term management.

[Q: 3855] OnExamination 2012 - Ophthalmology

A 17-year-old male with learning difficulties is brought for review by his worried parents after he described acute blurring of vision in his right eye.

Examination reveals ectopia lentis.

What is the most likely diagnosis?

- 1- Ehlers-Danlos syndrome
- 2- Homocystinuria
- 3- Maple syrup urine disease
- 4- Marfan's syndrome
- 5- Metachromatic leukodystrophy

Answer & Comments

Answer: 2- Homocystinuria

Ectopia lentis/ subluxation of the lens is associated with:

Ehlers-Danlos syndrome

Marfan's syndrome

Weill-Marchesani syndrome (short stature, skeletal abnormalities and ectopia lentis)

Refsum's disease.

In this case homocystinuria is likely to be due to the associated mental retardation.

Patients typically have fair skin with coarse hair, osteoporosis, mental retardation (nearly

50%), seizure disorder, marfanoid habitus, and and increased thromboembolic risk.

Metachromatic leukodystrophy is a lysosomal storage disorder characterised by lipid (sulfatide) accumulation in the central nervous system and associated with psychomotor retardation in infants with optic atrophy and blindness.

[Q: 3856] OnExamination 2012 - Ophthalmology

A 53-year-old man presented with a one week history of bilateral red eyes, which started in his right eye and after three days spread to his other eye.

He reports associated soreness, watering but no discharge or change in his vision. He states his symptoms were preceded by an upper respiratory tract infection. He has a history of ulcerative colitis and reports his father had glaucoma.

On examination his vision is normal and there are bilateral conjunctival follicles.

What is the diagnosis?

- 1- Acute angle closure glaucoma
- 2- Acute anterior uveitis
- 3- Bacterial conjunctivitis
- 4- Episcleritis
- 5- Viral conjunctivitis

Answer & Comments

Answer: 5- Viral conjunctivitis

Viral conjunctivitis causes redness, soreness and watering. In severe cases it can cause a keratitis which may affect vision.

It is highly contagious so patients should be advised to practise strict hand hygiene, to avoid sharing towels and to take time off work.

It is a self-limiting disease which may take several weeks to resolve. Patients are treated

with topical lubricants and some ophthalmologists give topical chloramphenicol to protect against secondary bacterial infections.

Other causes of follicular conjunctivitis include:

Chlamydial conjunctivitis - (but this is associated with mucopurulent discharge)

Molluscum contagiosum

Herpes simplex

Drop hypersensitivity

Parinaud's oculoglandular syndrome.

Atopy and contact lens wear are causes of papillae.

A. Acute angle closure glaucoma (AACG) is incorrect as this causes severe pain and blurring of vision. Other symptoms of AACG include headache, nausea, vomiting and haloes.

B. Acute anterior uveitis is incorrect as this causes pain, photophobia and blurring of vision. It is not a cause of follicular conjunctivitis.

C. Bacterial conjunctivitis is incorrect as this causes discharge.

D. Episcleritis is incorrect as it is not a cause of follicular conjunctivitis.

E. Viral conjunctivitis is correct.

[Q: 3857] OnExamination 2012 - Ophthalmology

A 24-year-old lady presented with anisocoria, with the right pupil larger than the left, both in a brightly lit room and in a dim lit room. Her mother noticed this only five days ago.

The anisocoria was less marked in the dim lit room. Deep tendon reflexes were present and brisk throughout.

She occasionally noted horizontal diplopia with a right sided headache. There was no ptosis. Visual acuity was 6/6 on the Snellen chart in both eyes.

Which one of the following statements is most accurate?

- 1- The diagnosis is Holmes-Adie's syndrome
- 2- The diagnosis of a brain tumour needs to be excluded urgently
- 3- The diagnosis of a posterior communicating artery aneurysm needs to be excluded urgently
- 4- The pathological (diseased) pupil is actually the left pupil, diagnosis being Argyll Robertson pupil
- 5- When doing a swinging light test of the pupils, a right relative afferent papillary defect is to be expected

Answer & Comments

Answer: 3- The diagnosis of a posterior communicating artery aneurysm needs to be excluded urgently

The history of anisocoria, with headaches and diplopia should ring alarm bells, in that a life-threatening posterior communicating artery aneurysm/berry aneurysm needs to be excluded urgently.

Anisocoria being an efferent problem will not give a relative afferent papillary defect.

Holmes-Adie syndrome is characterised by a tonic pupil, which is larger than normal and constricts slowly in bright light, and absent deep tendon reflexes (most marked in the Achilles tendon). It develops gradually, and is a benign condition. It is thought to be the result of a neurotrophic viral infection.

The sudden onset of the symptoms make a brain tumour less likely than an aneurysm.

Argyll Robertson pupils are typically bilateral and are small and irregular with an absent light reflex, prompt accommodation reflex

and slow response to mydriatics. The most common case is syphilis.

[Q: 3858] OnExamination 2012 - Ophthalmology

A 25-year-old man presented with night blindness and gradual deterioration of his peripheral visual fields bilaterally.

Ocular examination revealed bony spiculed lesions in the peripheral retina of both eyes with attenuated retinal blood vessels.

His only other past medical history is that of a first degree heart block.

Which one of the following statements is most correct?

- 1- There is a one in two chance of him passing this disease on to his offspring
- 2- There is a one in four chance of him passing this disease on to his offspring
- 3- There is a one in 10 chance of him passing this disease on to his offspring
- 4- There is a 100% chance of him passing this disease on to his offspring
- 5- There is no chance of him passing this disease on to his offspring

Answer & Comments

Answer: 5- There is no chance of him passing this disease on to his offspring

The diagnosis is Kearns-Sayre syndrome.

This is a mitochondrial inherited disease, and as such is only passed on by mothers to offspring.

It is a slowly progressive neuromuscular disorder associated with progressive external ophthalmoplegia and heart conduction defect.

Ocular manifestations include ptosis and peripheral retinal bony spiculed appearances.

[Q: 3859] OnExamination 2012 - Ophthalmology

A 75-year-old man, known to have ischaemic heart disease, with a previous history of alcohol abuse, presented with a one week history of deterioration of central vision in the right eye.

He denied any ocular pain or headache. An objective visual fields test was done and he was found to have a right central scotoma.

What is the most likely diagnosis?

- 1- Alcohol toxic amblyopia
- 2- Macular degeneration
- 3- Ocular ischaemic syndrome
- 4- Vitamin A deficiency
- 5- Vitamin B₁₂ deficiency

Answer & Comments

Answer: 2- Macular degeneration

This history is most in keeping with macular degeneration.

The relatively short history is more suggestive of wet age-related macular degeneration, which is actually a systemic problem, of which ischaemic heart disease is a risk factor.

Toxic amblyopia will more often give a centro-caecal scotoma.

Central scotoma here indicates that only the macula region is involved.

[Q: 3860] OnExamination 2012 - Ophthalmology

A 23-year-old man with an otherwise insignificant past medical history, presented with a sharp painful left eye over the last one day.

Ocular examination revealed a left mildly red eye with mild reduction of visual acuity.

There were no ocular discharges to note.

What is the most likely diagnosis?

- 1- Episcleritis
- 2- Herpetic keratitis
- 3- Iritis
- 4- Posterior uveitis
- 5- Scleritis

Answer & Comments

Answer: 2- Herpetic keratitis

Any of the above given diagnoses can occur in a young man, but the history is that of a sharp painful eye, as opposed to a dull achy eye.

Any sharp ocular pain is more suggestive of corneal/ocular surface pathologies, and hence herpetic keratitis is the best answer.

[Q: 3861] OnExamination 2012 - Ophthalmology

A 45-year-old asthmatic man presented with bilateral blurry vision of gradual onset over the last two months.

On examination he was found to have bilateral posterior subcapsular cataract, more so in the right than the left.

His other past medical history was that he had galactosaemia when he was still a baby, but this has since been treated. He is on bronchodilator inhalers and steroid inhalers to control his asthma. His oral medication includes amiodarone, aspirin and simvastatin.

What is the most likely cause of his cataracts?

- 1- Amiodarone
- 2- Galactosaemia
- 3- Inhaled bronchodilators
- 4- Inhaled steroids
- 5- Simvastatin

Answer & Comments

Answer: 4- Inhaled steroids

Inhaled steroids can cause cataracts.

Amiodarone causes vortex keratopathy.

Galactosaemia also does cause cataracts, but if the galactosaemia is treated, the cataract is reversible.

Inhaled bronchodilators and simvastatin are not known to cause cataracts.

[Q: 3862] OnExamination 2012 - Ophthalmology

A 42-year-old lady presented with a two week history of noticing both her eyes were skewed towards the temporal side. She denied ocular pain and headaches. Her visual acuity was 6/6 on the Snellen chart in both eyes.

She was not able to adduct both eyes, but up and down gaze was fine. She had two previous episodes of optic neuritis in the right eye. The last episode happened four months ago.

Her walking was normal, and her deep tendon reflexes were present. She also had recovered from gastroenteritis three weeks ago.

What is the most likely condition with which the patient had presented?

- 1- Chronic progressive external ophthalmoplegia
- 2- Internuclear ophthalmoplegia
- 3- Miller Fisher syndrome
- 4- Ocular myasthenia
- 5- Parinaud's syndrome

Answer & Comments

Answer: 2- Internuclear ophthalmoplegia

This is a case of wall-eyed bilateral internuclear ophthalmoplegia (WEBINO).

The history suggests a demyelinating process, and failure of ocular adduction in such cases should prompt the diagnosis of internuclear ophthalmoplegia.

[Q: 3863] OnExamination 2012 -
Infectious disease

Regarding pneumonia caused by Legionella pneumophila, which of the following is true?

- 1- Is associated with hyponatraemia
- 2- Is best treated with intravenous amoxicillin and clavulanic acid
- 3- Is common in AIDS patients
- 4- Is readily diagnosed by standard aerobic culture of sputum
- 5- Should be managed on the ward in a respiratory isolation cubicle

Answer & Comments

Answer: 1- Is associated with hyponatraemia

Legionella pneumophila is a Gram negative bacillus that is ubiquitous in the environment.

Human infection occurs when a sufficient inoculum of bacteria are aerosolised and inhaled. It usually affects middle-aged and elderly patients, often with underlying lung disease. It is more common in men (3:1).

A variety of environmental sources have been identified as reservoirs of Legionella and have been responsible for infection in humans, including air conditioners, humidifiers, shower units and hot tubs. Other factors that predispose to infection include smoking, alcoholism, old age, chronic illness and immunosuppression. It is not common in AIDS, but in severe disease there is an increased risk.

Infection causes a flu-like illness with a dry cough, headache, confusion and delirium. Gastrointestinal upset is common, with diarrhoea and ileus. Focal neurological signs can develop. Bloods often show a normal white cell count with lymphopenia (with or without thrombocytopenia, or pancytopenia). Sodium is often low, due to a syndrome of inappropriate antidiuretic hormone. 50% of patients have abnormal renal and liver

function, and acute kidney injury can develop. Creatinine kinase can be raised.

Legionellae do not grow on standard culture media, but require specific supplemented media; they grow best at a low pH. Diagnosis is most commonly with antigen testing in the urine, but direct fluorescent antibody staining or serology can be used.

Erythromycin or clarithromycin are the antibiotics of choice; alternatives include doxycycline, co-trimoxazole or ciprofloxacin.

[Q: 3864] OnExamination 2012 -
Infectious disease

Which of the following concerning Corynebacterium diphtheriae is correct?

- 1- Can cause skin infection
- 2- Infection is often complicated by myocardial fibrosis after recovery from severe infection
- 3- Is most unlikely to cause infection in an individual with a positive Schick test
- 4- Mitis strain is generally more virulent than the intermedius strain
- 5- Toxin is better absorbed through the anterior nasal than the pharyngeal mucosa

Answer & Comments

Answer: 1- Can cause skin infection

Corynebacterium diphtheriae is a Gram positive, non-spore-forming, pleomorphic bacteria that is also a facultative anaerobe. It causes diphtheria in humans. There are three recognised strains of C.diphtheria: gravis, intermedius and mitis. Intermedius is thought to be the one most associated with the exotoxin and is more virulent than the mitis strain. Diphtheria is transmitted from person to person, with human beings the main reservoir. The Schick test involves the intradermal injection of a small amount of diphtheria toxin into the arm of a person. If

positive a wheal develops, which indicates the patient is susceptible to diphtheria. It is no longer used in routine clinical practice in the UK.

Typically diphtheria attacks the respiratory system, but may also affect the skin, conjunctiva and external genitalia. Signs and symptoms include sore throat, fever, and swelling of lymph nodes in the neck and general malaise. As the disease progresses diphtheria toxin is secreted. This destroys the membrane surface of the affected areas and replaces them with a greyish tough leathery "pseudomembrane" made of dead tissue, leukocytes and bacteria. The classical signs which may be described in examination questions include the dense grey pseudomembrane, which can occur in any portion of the respiratory tract (characteristically the posterior pharynx) and a 'bulls neck' which results from cervical lymphadenopathy and mucosal swelling.

Cutaneous diphtheria presents with non-healing ulcers covered with a grey membrane, which can develop bacterial co-infection. If isolated the disease is indolent, but the ulcers can act as a reservoir which can subsequently lead to pharyngeal infection.

Anterior nasal diphtheria usually presents in a similar fashion to the common cold, as absorption of the toxin here is minimal. Pharyngeal, tonsillar and laryngeal diphtheria results in higher absorption of toxin into the bloodstream and therefore more severe manifestations.

If absorbed systemically, toxin can also affect the heart, nerves and other organs in the body causing heart failure, nerve damage or suffocation. Cardiac involvement is usually in the form of a cardiomyopathy and myositis, which is evident from the 10-14th day and may lead to arrhythmias. This accounts for 50% of deaths, but myocardial fibrosis affects a minority infected with diphtheria.

Management of suspected cases should include isolation, securing a definitive airway, cardiac monitoring, and erythromycin or penicillin promptly. Antitoxin is available in the USA.

Diphtheria is a notifiable disease in the UK.

[Q: 3865] OnExamination 2012 - Infectious disease

A 35-year-old female who returned from holiday in Costa Rica two months ago now reports having ulceration around her neck with cervical lymphadenopathy.

The lesion was initially a papule then it turned into a nodule and is now an ulcer. The ulcer is pruritic with raised undulated borders. The thin smears of dermal scraping show amastigotes when stained with Giemsa.

What is the most likely aetiological agent?

- 1- Cutaneous leishmaniasis
- 2- Lepromatous leprosy
- 3- Mycobacterium tuberculosis ulceration
- 4- Visceral leishmaniasis
- 5- Visceral ulceration

Answer & Comments

Answer: 1- Cutaneous leishmaniasis

Mycobacterium tuberculosis ulceration usually has undermined edges. They will not have any amastigotes in stain.

Visceral ulceration is the wrong answer.

Visceral leishmaniasis is the wrong answer as it presents differently. The patient's skin may turn grey with hepatosplenomegaly and some may have a lymphadenopathy.

Lepromatous leprosy usually forms poorly margined, multiple infiltrated nodules and plaques of diffuse infiltration.

[Q: 3866] OnExamination 2012 -

Infectious disease

A 20-month-old baby is brought to the Emergency department with a two day history of irritability, fever and non-blanching rash. BP was normal.

What is the likeliest diagnosis?

- 1- H. influenzae
- 2- L. monocytogenes
- 3- N. meningitidis
- 4- S. aureus
- 5- Streptococcus pneumoniae

Answer & Comments

Answer: 3- N. meningitidis

Meningococcal disease is an important cause of severe infection in young infants. Early recognition and treatment is essential for a favourable outcome.

Although other organisms can cause meningitis, N. meningitidis is the likeliest cause.

At 20 months, the infant should have been immunised against H. influenzae serotype B.

[Q: 3867] OnExamination 2012 - Infectious disease

A 24-year-old IV drug abuser presents with jaw spasm to the emergency department. She says she re-used a heroin needle a few days ago and a couple of her sites look infected.

She has suffered recurrent admissions with pneumonia over the past two years and has been using heroin for the past four years.

On examination she is pyrexial 37.8°C. She has jaw spasm, significant neck stiffness and looks in pain. Examination of her groin and left antecubital fossa reveals discharging sinuses from where she has injected heroin previously.

Investigations show

Hb 11.4 g/dl(13.5-18)

WCC $10.8 \times 10^9/L$ (4-10)

PLT $179 \times 10^9/L$ (150-400)

Na 139 mmol/l (134-143)

K 4.5 mmol/l (3.5-5)

Cr 129 $\mu\text{mol/l}$ (60-120)

She is given immunoglobulin.

Which of the following antibiotic treatments is most appropriate in addition?

- 1- Chloramphenicol
- 2- Ciprofloxacin
- 3- Erythromycin
- 4- Metronidazole
- 5- Oxytetracycline

Answer & Comments

Answer: 4- Metronidazole

This woman is suffering from tetanus as a result of infection via a contaminated drug injecting needle.

Initial management of choice is anti-tetanus immunoglobulin, followed in this case by the addition of systemic antibiotics, either metronidazole or benzylpenicillin, and debridement of any wound if required.

Diazepam, neuromuscular blockade, and intubation may all be required during the acute phase.

Over the longer term, muscle spasms and ankle clonus can persist for many months.

[Q: 3868] OnExamination 2012 - Infectious disease

Following your morning surgery, you receive a telephone call from the lab at the local hospital regarding an 82-year-old patient of yours whom you admitted from her nursing home with headache, photophobia and neck stiffness. When you saw her, her temperature was 39.0°C, pulse rate 115 beats/min and

there were no skin rashes or focal neurological signs. Her Glasgow coma scale was 15/15.

Following admission, CSF was obtained and Gram stain showed Gram-negative coccobacilli, subsequent culture confirms a *Haemophilus influenzae* meningitis.

What chemoprophylaxis should be offered to the nurses at her home?

- 1- Azithromycin
- 2- Ceftriaxone
- 3- Ciprofloxacin
- 4- No chemoprophylaxis required
- 5- Rifampicin

Answer & Comments

Answer: 5- Rifampicin

Close contacts of *Haemophilus influenzae* meningitis should receive rifampicin; children under two years should be vaccinated.

[Q: 3869] OnExamination 2012 - Infectious disease

An 18-year-old student presented to hospital two days after returning from visiting family in India.

Within twenty four hours of his return to the United Kingdom he suddenly developed profuse watery diarrhoea. Initially he did not have any nausea, vomiting or stomach cramps, but these developed within a day. He described the diarrhoea as looking like cloudy water but without any blood or mucus. He was opening his bowels over 20 times per day.

On examination he looked pale; he was afebrile. Skin turgor was reduced and mucous membranes were dry.

Stool culture revealed a growth of *Vibrio cholerae*.

Which is the most appropriate antibiotic to administer?

- 1- Ceftriaxone

- 2- Doxycycline
- 3- Meropenem
- 4- Metronidazole
- 5- Piperacillin plus gentamicin

Answer & Comments

Answer: 2- Doxycycline

Cholera has a short incubation period of 24-48 hours.

The illness begins with the sudden onset of painless, watery diarrhoea. The diarrhoea may be accompanied later by abdominal cramps, nausea and vomiting. Patients are usually afebrile. The diarrhoea is typically described as having the appearance of rice water and a faintly fishy smell. The diarrhoea may be copious and result in hypovolaemic shock unless fluids are administered.

The primary aim of treatment is to restore fluid balance; antibiotics have a secondary role. However, antibiotics have been shown to reduce fluid loss and hasten clearance of the organism from the gut.

Appropriate antibiotics include

Tetracycline

Doxycycline

Ciprofloxacin

Erythromycin

Co-trimoxazole.

Tetracycline is usually the first line drug of choice, although resistance is emerging in certain parts of the world.

[Q: 3870] OnExamination 2012 - Infectious disease

A 51-year-old lady presented to hospital with a two day history of malaise and headache.

On the day of admission the headache had become more intense and was associated with pain in her neck.

Her husband reported that she had also been febrile and confused at times. She had previously been well and had no significant past medical history.

On examination, she was febrile 38.1°C, looked unwell and was photophobic. Kernig's and Brudzinski's signs were positive. The fundi were normal with no evidence of papilloedema.

Following a normal CT scan a lumbar puncture was performed and CSF analysis showed:

White cells 200/mm³

Red cells 2/mm³

CSF protein 0.9 g/l (0.15-0.45)

CSF glucose 1.6 mmol/l (3.3-4.4)

Plasma glucose 5.3 mmol/l (3.0-6.0)

What is the most likely causative organism?

- 1- Escherichia coli
- 2- Listeria monocytogenes
- 3- Mycobacterium tuberculosis
- 4- Streptococcus pneumoniae
- 5- Streptococcus pyogenes

Answer & Comments

Answer: 4- Streptococcus pneumoniae

The most common causes of bacterial meningitis in persons over 50 years of age are:

Streptococcus pneumoniae

Neisseria meningitidis

Listeria monocytogenes

Gram negative bacilli.

Although this question tries to establish whether candidates are aware of the most common cause of meningitis in this group,

some questions in the examination give additional clues as to the cause of meningitis.

Physical examination may provide clues to the aetiology of meningitis in affected patients:

Morbilloform rash with pharyngitis and lymphadenopathy may suggest a viral aetiology (Epstein-Barr virus [EBV], cytomegalovirus [CMV], adenovirus, human immunodeficiency virus [HIV]).

Macules and petechiae that rapidly evolve into purpura suggest meningococcaemia (with or without meningitis).

Vesicular lesions in a dermatomal distribution suggest Varicella zoster virus.

Genital vesicles suggest Herpes simplex virus (HSV)-2 meningitis.

Sinusitis or otitis suggest direct extension into the meninges, usually with Streptococcus pneumoniae and Haemophilus influenzae.

Rhinorrhoea or otorrhoea suggest a cerebrospinal fluid (CSF) leak from a basilar skull fracture, with meningitis most commonly caused by Streptococcus pneumoniae.

Hepatosplenomegaly and lymphadenopathy suggest a systemic disease, including viral (for example, mononucleosis-like syndrome in EBV, CMV, and HIV) and fungal (for example, disseminated histoplasmosis) disease.

The presence of a murmur suggests infective endocarditis with secondary bacterial seeding of the meninges.

Evidence of parotitis is observed in some cases of mumps meningitis.

Kernig's sign (pdf)

In a supine patient, flex the hip to 90° while the knee is flexed at 90°. An attempt to further extend the knee produces pain in the hamstrings and resistance to further extension.

Brudzinski's sign (pdf)

Passively flex the neck while the patient is in a supine position with extremities extended. This manoeuvre produces flexion of the hips in patients with meningeal irritation.

[Q: 3871] OnExamination 2012 - Infectious disease

A 17-year-old male presented to casualty complaining of difficulty breathing. He had been brought to hospital by ambulance, having collapsed shortly after being stung on the hand by a bee.

On examination, his blood pressure was 80/40 mmHg, and facial swelling was noted.

Which one of the following investigations is most likely to confirm the nature of the reaction?

- 1- Haemolytic complement (CH50) level
- 2- Plasma tryptase activity
- 3- Serum complement C3 level
- 4- Serum total IgE level
- 5- Serum venom-specific IgE level

Answer & Comments

Answer: 2- Plasma tryptase activity

Type I hypersensitivity, also known as immediate or anaphylactic hypersensitivity, usually takes 15 - 30 minutes from the time of exposure to the antigen. The reaction may cause a range of symptoms from minor inconvenience to death.

The reaction involves preferential production of IgE in response to certain antigens which in turn initiates a sequence of events leading to the release of various pharmacologically active substances that are responsible for the clinical features.

Diagnostic tests include skin tests, measurement of total IgE and specific IgE antibodies against the suspected allergens. However, this question asks which of the

following tests would provide confirmatory information and that would be tryptase.

Tryptase is a neutral protease stored in mast cell secretory granules that is secreted by human mast cells. Levels in normal blood are undetectable (< 1 ng/ml). Elevated serum levels demonstrate that mast cell activation with mediator release has occurred whether triggered by IgE-mediated anaphylaxis or non-IgE-mediated anaphylactoid reactions. The greater the severity of anaphylaxis, the more likely that serum -tryptase levels will be elevated.

[Q: 3872] OnExamination 2012 - Infectious disease

You are considering starting a patient on griseofulvin.

Which of the following statements concerning its pharmacology is true?

- 1- It is active against Aspergillus
- 2- It is active against Candida albicans
- 3- It is associated with drug-induced Stevens-Johnson syndrome
- 4- It is used for a maximum of two weeks
- 5- It should not be used in renal failure

Answer & Comments

Answer: 3- It is associated with drug-induced Stevens-Johnson syndrome

For griseofulvin and Stevens-Johnson syndrome read Am J Emerg Med 1984;2:129-135. Many other drugs are implicated in causing Stevens-Johnson syndrome.

Griseofulvin is not active against Candida albicans. It is active against trichophytons (tinea) and other dermatophytes.

It is metabolised in the liver (note also, it is an enzyme inducer). Only 0.1-0.2% is excreted in urine.

Treatment with griseofulvin is often needed for a long period, sometimes years, depending on the rate of nail growth.

[Q: 3873] OnExamination 2012 - Infectious disease

An 87-year-old woman was referred to clinic with a two month history of alternating constipation and diarrhoea, night sweats and fatigue. The patient was not sure if she had lost any weight.

On examination she appeared thin and pale. Her pulse was 80/minute and regular. A systolic murmur was audible at the apex, radiating to the axilla. No diastolic murmurs were heard.

Investigations revealed blood cultures to be positive, and transthoracic echocardiogram revealed a vegetation on the mitral valve.

What is the most likely causative organism in this case?

- 1- Coagulase-negative Staphylococcus
- 2- Staphylococcus aureus
- 3- Streptococcus bovis
- 4- Streptococcus mitis
- 5- Streptococcus viridans

Answer & Comments

Answer: 3- Streptococcus bovis

This patient has endocarditis.

In addition to the symptoms that might be attributed to endocarditis (fatigue, night sweats), she also has a history of altered bowel habit that is very suggestive of an underlying malignancy.

Streptococcus bovis is a normal commensal of the gastrointestinal (GI) tract. However, S. bovis bacteraemia and endocarditis have a strong association with GI malignancy.

Coagulase-negative staphylococcal endocarditis is exceptionally rare in native

valve endocarditis, though it is the commonest cause of prosthetic valve endocarditis in the postoperative period.

Staphylococcus aureus endocarditis is typically the result of a focus of staphylococcal infection (for example, skin abscess).

Streptococcus mitis endocarditis and viridans streptococci (which include S. mitis) are normal commensals of the oropharynx and GI tract.

Endocarditis is usually associated with poor dental hygiene; overall, Streptococcus viridans accounts for ~40% of cases of endocarditis.

[Q: 3874] OnExamination 2012 - Infectious disease

Which of the following is a feature of vancomycin-resistant enterococci?

- 1- Cause resistant infective diarrhoea
- 2- Produce an enzyme that inactivates vancomycin
- 3- May be found in healthy community volunteers not recently hospitalised
- 4- High dose ampicillin is the treatment of choice
- 5- Are commonly vancomycin-dependent

Answer & Comments

Answer: 3- May be found in healthy community volunteers not recently hospitalised

A. When they cause clinical problems they are usually urinary tract infections (UTI), bacteraemia, wound infections, neonatal infections, endocarditis, etc.

B. They alter peptidoglycan precursors used to build cell walls. Vancomycin binds to D-alanyl-D-alanine but the resistant enterococci have D-alanyl-D-lactate or D-alanine terminating precursors. They acquire genes that produce enzymes to change the precursors.

C. Two per cent in the United Kingdom general practice, 28% in Belgium. Community reservoir in meat, poultry and perhaps cheese.

D. Only if the MIC (minimum inhibitory concentration) of ampicillin is not too high. Anecdotal evidence exists for its use in *E. faecalis* endocarditis. (20g / day).

E. Some strains only. An explanation for this curious process is that there is an inability to produce cell walls because the vancomycin-sensitive precursor genes have been turned off and the resistant ones only appear in the presence of vancomycin.

(Source: *Am J Med* 1997;102:284-293)

[Q: 3875] OnExamination 2012 - Infectious disease

You review a 30-year-old HIV positive man with *Pneumocystis carinii* pneumonia (PCP).

Blood gases reveal a pO_2 of 55 mmHg (75-100) whilst breathing 28% oxygen.

Which of the following would be indicated in the treatment?

- 1- Atovaquone
- 2- Clindamycin
- 3- Leucovorin
- 4- Pentamidine
- 5- Trimethoprim-sulphamethoxazole

Answer & Comments

Answer: 5- Trimethoprim-sulphamethoxazole

This patient has severe PCP as suggested by the hypoxia (pO_2 less than 70). He should be treated with high percentage oxygen and the drug of choice is high dose IV co-trimoxazole (trimethoprim-sulphamethoxazole).

If allergic to co-trimoxazole, IV pentamidine or clindamycin are appropriate.

IV leucovorin and oral atovaquone are further options but are not first line therapies.

Prednisolone has been shown to reduce mortality substantially in patients with a PO_2 <60 mmHg.

[Q: 3876] OnExamination 2012 - Infectious disease

A 32-year-old woman complains of an offensive clear yellow vaginal discharge, with associated vulval itch and soreness. She admits to beginning a relationship with a new partner some four weeks earlier.

On examination her vulva looks slightly erythematous and there is a clear discharge that has a fishy odour.

Which of the following is the most likely diagnosis?

- 1- Bacterial vaginosis
- 2- *C. trachomatis*
- 3- Herpes simplex infection
- 4- *N. gonorrhoeae*
- 5- *T. vaginalis*

Answer & Comments

Answer: 5- *T. vaginalis*

The answer is E, *T. vaginalis*.

The clinical picture described fits entirely with infection with the anaerobic flagellated protozoan *Trichomonas vaginalis*.

Trichomoniasis differs from non-infective vaginosis, with respect to a yellowish colour to the discharge and associated vulval irritation.

A large dose of metronidazole (2 g as a single course), or a seven day course at lower dose is the treatment of choice. Patients should of course also be screened for other sexually transmitted infections.

Partners should be identified and also screened for infection as men rarely exhibit symptoms of a *T. vaginalis* infection.

The epithelial damage caused by *T. vaginalis* increases susceptibility to HIV virus infection and transmission.

Whilst bacterial vaginosis is also associated with a discharge with a fishy odour, classically there is no soreness or irritation associated with it.

[Q: 3877] OnExamination 2012 - Infectious disease

A 31-year-old African man presented with a history of fever, night sweats, shortness of breath and weight loss for two months. His chest radiograph showed a moderately severe left pleural effusion only. He consented to an HIV test which was positive.

What is the most likely cause of pleural effusion?

- 1- Hodgkin's lymphoma
- 2- Pleural tuberculosis
- 3- Pneumocystis jirovecii pneumonia (PCP)
- 4- Pulmonary aspergillosis
- 5- Pulmonary Kaposi's sarcoma

Answer & Comments

Answer: 2- Pleural tuberculosis

Pleural tuberculosis is the most likely cause in an HIV positive African man with a two month history of weight loss. His pleural effusion is due to pleural tuberculosis (extra pulmonary tuberculosis).

Hodgkin's lymphoma can cause pleural effusion due to pleural involvement but it is often associated with mediastinal mass. His chest radiograph showed only pleural effusion. Non-Hodgkin's lymphoma (not Hodgkin's lymphoma) is commonly associated with these patients.

PCP does not cause pleural effusion. It typically causes bilateral reticular shadows

from the hila without any hilar lymph node enlargement or pleural effusion.

Pulmonary aspergillosis shows infiltrative lesions but it does not typically cause pleural effusion.

Pulmonary Kaposi's sarcoma can cause pleural effusion by involving the pleura, but it often causes coarse irregular nodular lesions in the lungs.

Reference:

El-Gadi SM, Banks J, Yoganathan K. Kaposi sarcoma presenting as severe haemoptysis. Genitourin Med. 1997 Dec; 73(6): 575-6.

[Q: 3878] OnExamination 2012 - Infectious disease

A young girl returns from a trip to India with a protracted history of watery diarrhoea.

Giardiasis is suspected but three stool samples are negative.

What is the best investigation to confirm Giardia as a diagnosis?

- 1- CT abdomen
- 2- Rectal biopsy
- 3- Serum IgM Giardia antibodies
- 4- Small intestine biopsy
- 5- Stool microscopy

Answer & Comments

Answer: 4- Small intestine biopsy

Giardia may be difficult to diagnose from stool samples alone. Concentration techniques and optimising sample preparation may improve stool sample yield.

However, parasitic antigen detection in stool is at least as sensitive and specific as good microscopic examination of stool, and may be easier to perform.

In this case detection of Giardia may be achieved by sampling of duodenal fluid, or small bowel biopsy.

[Q: 3879] OnExamination 2012 - Infectious disease

Three elderly patients presented with cough, fever and general malaise on return from holiday to Spain.

The group of 50 had travelled together, engaging in visits to hillside forestry, and fishing in mountain streams. They had been housed in different hotels. The three people who presented with illness all stayed in the same hotel.

Which of the following organisms is most likely to be responsible for their illness?

- 1- Borrelia burgdorferi
- 2- Legionella pneumophila
- 3- Leptospira icterohaemorrhagiae
- 4- Mycoplasma pneumoniae
- 5- Pneumococcus

Answer & Comments

Answer: 2- Legionella pneumophila

This is a typical story for legionnaires' disease caused by Legionella pneumophila.

The condition was described first in a veteran's legion conference in a similar fashion to the above description.

Contaminated air conditioning units are often to blame.

Weil's disease is unlikely given the story as is Lyme disease (Borrelia burgdorferi).

[Q: 3880] OnExamination 2012 - Infectious disease

A 56-year-old man diagnosed with systemic inflammatory response syndrome (SIRS)

secondary to pneumonia is admitted to the high dependency unit.

On examination, he has a temperature of 39°C, a respiratory rate of 30/min, has a pulse of 109 beats/min and a blood pressure of 89/74 mmHg despite receiving IV fluids and urine output of 25 ml/hour after catheterisation.

Which of the following should be instituted immediately and should be accomplished within the first six hours of presentation?

- 1- Administer drotrecogin alfa (activated protein C)
- 2- Administer intravenous furosemide
- 3- Administer low dose steroids
- 4- Institute tight glucose control
- 5- Obtain blood cultures prior to antibiotic administration

Answer & Comments

Answer: 5- Obtain blood cultures prior to antibiotic administration

The Surviving Sepsis Campaign (a partnership of the Society of Critical Care Medicine, the European Society of Intensive Care Medicine, and the International Sepsis Forum) has teamed up with the Institute for Healthcare Improvement to develop severe sepsis bundles. A 'bundle' is a group of interventions related to a disease process that, when executed together, result in better outcomes than when implemented individually.

Sepsis Resuscitation Bundle

(Should begin immediately, but must be accomplished within the first six hours of presentation.)

Serum lactate measured.

Blood cultures obtained prior to antibiotic administration.

From the time of presentation, broad-spectrum antibiotics administered within

three hours for ED admissions and one hour for non-ED ICU admissions.

In the event of hypotension and/or lactate > 4 mmol/l (36 mg/dl):

Deliver an initial minimum of 20 ml/kg of crystalloid (or colloid equivalent).

Apply vasopressors for hypotension not responding to initial fluid resuscitation to maintain mean arterial pressure (MAP) > 65 mm Hg.

In the event of persistent hypotension despite fluid resuscitation (septic shock) and/or lactate > 4 mmol/l (36 mg/dl):

Achieve central venous pressure (CVP) of > 8 mm Hg.

Achieve central venous oxygen saturation (ScvO₂) of > 70%.

Sepsis Management Bundle

(To be accomplished as soon as possible may be completed within twenty-four hours of presentation.)

Low-dose steroids administered for septic shock in accordance with a standardised ICU policy.

Glucose control maintained > lower limit of normal, but < 150 mg/dl (8.3 mmol/l).

Inspiratory plateau pressures maintained < 30 cm H₂O for mechanically ventilated patients

Drotrectogin alpha (activated protein C) used to be recommended by NICE for the treatment of severe sepsis. However, in October 2011 the company withdrew this from the market following the results of the PROWESS-SHOCK study, which showed there was no statistically significant reduction in 28-day all-cause mortality in patients with septic shock.

[Q: 3881] OnExamination 2012 - Infectious disease

During an outbreak of influenza A, which of the following may provide appropriate prophylaxis for healthcare workers?

- 1- Amantadine
- 2- Ganciclovir
- 3- Lamivudine
- 4- Oseltamivir
- 5- Zidovudine

Answer & Comments

Answer: 4- Oseltamivir

Oseltamivir (Tamiflu) may be used in the prophylactic treatment of healthcare workers during flu epidemics.

However, long term treatment does run a risk of resistance.

[Q: 3882] OnExamination 2012 - Infectious disease

Transplacental transmission of all of the following organisms is a recognised cause of fetal malformations and disease except which of the following?

- 1- Cytomegalovirus
- 2- Mumps
- 3- Rubella
- 4- Toxoplasma gondii
- 5- Varicella zoster virus

Answer & Comments

Answer: 2- Mumps

Cytomegalovirus in pregnancy can cause fetal abnormalities or abortion.

Varicella is rare in pregnancy but can be severe and cause intrauterine death of the fetus.

Congenital toxoplasmosis usually results from an acute maternal infection during pregnancy.

Measles and mumps cause only mild maternal infection and do not pose a serious problem to the fetus.

[Q: 3883] OnExamination 2012 - Infectious disease

A 42-year-old man with advanced HIV disease presented with a tonic-clonic seizure. He had been diagnosed with HIV 10 years previously, but had elected not to take antiretroviral therapy.

A CT scan of his brain showed a 2 cm ring-enhancing lesion in the right parietal lobe.

What is the probable causative agent?

- 1- Cryptococcus neoformans
- 2- Mycobacterium avium intracellulare
- 3- Mycobacterium tuberculosis
- 4- Pneumocystis carinii
- 5- Toxoplasma gondii

Answer & Comments

Answer: 5- Toxoplasma gondii

This is a typical presentation with AIDS-related cerebral toxoplasmosis.

The differential diagnosis of ring-enhancing lesions on CT in a patient with AIDS include:

Cerebral toxoplasmosis

Abscesses

Metastases

Atypical CNS lymphoma.

Cryptococcus typically causes a meningitis.

CNS infections with the remaining organisms are rare in AIDS.

[Q: 3884] OnExamination 2012 - Infectious disease

Which of the following is true of the antibiotic combination quinupristin and dalbapristin?

- 1- Administered orally.
- 2- Effective against multi-resistant Staph. aureus
- 3- Effective against resistant mycobacterium TB.
- 4- Indicated in subjects with chronic renal impairment.
- 5- Particularly effective in the treatment of Pseudomonas infection in cystic fibrosis.

Answer & Comments

Answer: 2- Effective against multi-resistant Staph. aureus

Quinupristin and dalbapristin are a synergistic combination of a streptogramin A and B respectively.

They are effective against Gram positive aerobes and are particularly useful against resistant Strep. pneumoniae and Staph. aureus.

They can be administered only via a central line.

[Q: 3885] OnExamination 2012 - Infectious disease

You are an occupational health physician and have been asked by an anxious employee about contraindications to pertussis immunisation.

Which of the following is a contraindication?

- 1- Cow's milk protein intolerance.
- 2- Eczema
- 3- Fever to 39.5°C following the first dose.
- 4- Hydrocephalus
- 5- Redness of >2.5cm at the injection site after the first dose.

Answer & Comments

Answer: 3- Fever to 39.5°C following the first dose.

True contraindications to pertussis immunisation include:

Acute illness - until recovered

Previous reaction to pertussis:

Local: an extensive area of redness and swelling which becomes indurated, involving most of the anterolateral surface of the thigh or a major part of the circumference of the upper arm

General: fever equal to or more than 39.5°C within 48 hours of vaccine, anaphylaxis, bronchospasm, laryngeal oedema, generalised collapse, prolonged hyporesponsiveness, prolonged inconsolable or high-pitched screaming of more than four hours, convulsions or encephalopathy occurring within 72 hours.

A personal family history of allergy is not a contraindication, nor are stable neurological conditions such as cerebral palsy or spina bifida.

In patients who have had a previous reaction, immunisations should be completed with DT vaccine, and acellular vaccine considered.

[Q: 3886] OnExamination 2012 - Infectious disease

A 19-year-old man returned to the United Kingdom two weeks after working in a refugee camp in sub-Saharan Africa.

On examination he was febrile, dyspnoeic and widespread inspiratory crackles were present. He had an extensive maculo-papular rash, conjunctivitis, generalised stomatitis and some bluish-grey spots on the buccal mucosa.

What is the most likely diagnosis?

- 1- Epidemic typhus
- 2- Epstein-Barr virus infection

3- Leptospirosis

4- Measles

5- Parvovirus infection

Answer & Comments

Answer: 4- Measles

Although seldom seen in countries in which a vaccine is available, measles is a major health problem in refugee camps in Africa.

The clinical picture described is characteristic.

The major complications of measles involve the respiratory tract and central nervous system.

Pneumonia may be caused by the virus itself or through bacterial superinfection.

[Q: 3887] OnExamination 2012 - Infectious disease

A 72-year-old female presents with a two month history of poor appetite, lethargy, intermittent fever and night sweats. She has poor dentition and over the last 12 months has required dental extraction.

On examination, a murmur consistent with mitral regurgitation is heard. A transthoracic echocardiogram reveals a vegetation on the mitral valve.

What is the likeliest cause of her endocarditis?

- 1- C. burnetii
- 2- E. faecalis
- 3- MRSA
- 4- S. aureus
- 5- S. mutans

Answer & Comments

Answer: 5- S. mutans

S. mutans is a member of the viridans Streptococcus group and a common cause of bacterial endocarditis.

Poor dentition and procedures such as dental extraction are associated with transient viridans streptococcal bacteraemia.

In the presence of a pre-existing cardiac lesion this may have caused infective endocarditis.

[Q: 3888] OnExamination 2012 - Infectious disease

A 72-year-old male presents with a two month history of poor appetite, lethargy, intermittent fever and night sweats. Four months previously he had undergone TURP for benign prostatic hypertrophy.

On examination a murmur consistent with mitral regurgitation is heard. A transthoracic echocardiogram reveals a vegetation on the mitral valve.

What is the likeliest cause of his endocarditis?

- 1- C. burnetii
- 2- E. faecalis
- 3- MRSA
- 4- S. aureus
- 5- S. mutans

Answer & Comments

Answer: 2- E. faecalis

E. faecalis is a common cause of bacterial endocarditis following a urological procedure.

Urological procedures, such as transurethral resection of the prostate (TURP), may cause a transient E. faecalis bacteraemia.

In the presence of a pre-existing cardiac lesion this may have caused infective endocarditis.

[Q: 3889] OnExamination 2012 - Infectious disease

A 21-year-old man returns from a trip to Spain with a group of male friends, complaining of pus-like urethral discharge and pain on passing urine. He admits to unprotected sex

with three different female partners during the course of the holiday.

On examination he is afebrile, his BP is 115/70 mmHg, and his pulse is 70 and regular. Respiratory and abdominal examinations are unremarkable.

You can easily express pus-like discharge from his urethral meatus.

Investigations show:

Haemoglobin 13.9 g/dl (13.5-17.7)

White cell count $9.6 \times 10^9/L$ (4-11)

Platelets $282 \times 10^9/L$ (150-400)

Serum Sodium 139 mmol/l (135-146)

Serum Potassium 4.4 mmol/l (3.5-5)

Creatinine 88 micromol/l (79-118)

Microscopy of pus sample Gram negative diplococci

Which of the following is the most appropriate treatment for him?

- 1- Ceftriaxone 250 mg IM as a single dose
- 2- Ciprofloxacin 500 mg BD for 7 days
- 3- Clarithromycin 500 mg PO BD for 7 days
- 4- Doxycycline 100 mg PO daily for 7 days
- 5- Penicillin V 500 mg PO for 7 days

Answer & Comments

Answer: 1- Ceftriaxone 250 mg IM as a single dose

The answer is A, ceftriaxone 250 mg IM as a single dose.

Due to questions of compliance and the need for definitive treatment, the optimal way to deliver treatment for gonorrhoea is with one IM injection.

This patient will also require referral to the local GUM clinic for a full sexual health screen to rule out co-existent pathogens apart from gonococcus.

[Q: 3890] OnExamination 2012 -
Infectious disease

A 32-year-old woman comes to the clinic. She complains of very foul smelling diarrhoea, abdominal bloating and excessive flatulence some two weeks after returning from a holiday to Mauritius with her husband. They admit to having eaten food from street vendors on a number of occasions during the course of the holiday.

On examination her BP is 122/72 mmHg, there is no postural drop. Her pulse is 70 and regular. Respiratory examination is normal and abdominal examination reveals a soft but mildly distended abdomen, with active bowel sounds.

Investigations show

Haemoglobin 11.8 g/dl(11.5-16.5)

White cells $8.9 \times 10^9/L$ (4-11)

Platelets $192 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

Albumin 40 g/l (35-50)

Which of the following is the most likely diagnosis?

- 1- Campylobacter
- 2- Giardiasis
- 3- Salmonella
- 4- Shigella
- 5- Tropical sprue

Answer & Comments

Answer: 2- Giardiasis

This patient's history is consistent with Giardia lamblia infection, particularly with respect to her abdominal bloating, diarrhoea, and excess production of gas.

It is transmitted via the faecal oral route, and she is likely to have picked up the infection from eating food from a street vendor.

Diagnosis was traditionally based on stool microscopy looking for trophozoites or cysts, but antigen tests are now also available.

The infection responds to treatment with either metronidazole or tinidazole, and once treated does not usually recur.

[Q: 3891] OnExamination 2012 -
Infectious disease

A 27-year-old man presents with pulmonary tuberculosis. He was released from a Chinese jail where he was a prisoner for some six years and has now applied for residency in the United Kingdom.

On examination you notice that he has a number of violaceous plaques on both lower limbs. Oral candidiasis is also present.

Investigations show:

Haemoglobin 11.4 g/dl(13.5-18)

White cell count $4.2 \times 10^9/L$ (4-10)

Platelets $195 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 120 $\mu\text{mol/l}$ (60-120)

Which of the following is the most likely cause of his skin changes?

- 1- Cocksackie B
- 2- Herpes zoster
- 3- Human herpes virus 6
- 4- Human herpes virus 8
- 5- Human papilloma virus

Answer & Comments

Answer: 4- Human herpes virus 8

The skin condition that this patient is suffering from is suggestive of Kaposi's sarcoma in a

patient with HIV infection (pulmonary tuberculosis and oral candidiasis).

HHV-8 DNA was first sequenced from Kaposi's in the early '90s. Human herpes virus 8 is also associated with primary effusion lymphoma (a rare lymphoma of serous cavities) and Castleman's disease.

AIDS-related Kaposi's sarcoma becomes smaller as immune function improves such as with treatment with highly active antiretroviral therapy (HAART).

In some circumstances chemotherapy may be added to HAART. Radiotherapy may be used to treat painful or highly visible lesions.

[Q: 3892] OnExamination 2012 - Infectious disease

A 48-year-old African man with HIV was prescribed a combination of antiretroviral therapy. He developed increased diffuse pigmentation of the nails in both hands and toes.

What is the most likely cause of the increased pigmentation of the nails?

- 1- Efavirenz
- 2- Lamivudine
- 3- Nevirapine
- 4- Tenofovir
- 5- Zidovudine

Answer & Comments

Answer: 5- Zidovudine

Zidovudine causes increased pigmentation of the nails in black patients.

Efavirenz causes central nervous system toxicity not hyperpigmentation.

Lamivudine does not normally cause hyperpigmentation of nails but it can occasionally cause hyperpigmentation of the skin in black people.

Nevirapine does not cause hyperpigmentation of skin but can cause acute hepatitis and skin rash.

Tenofovir can cause proximal tubular damage hence Fanconi-like syndrome.

Reference:

Furth PA, Kazakis AM. Nail pigmentation changes associated with azidothymidine (zidovudine). *Ann Intern Med.* 1987 Sep; 107(3): 350.

[Q: 3893] OnExamination 2012 - Infectious disease

A 47-year-old man presents with progressive right hand swelling two days after being bitten by a dog.

On examination there is a puncture wound with pus over the dorsum of the hand, cellulitis, ascending lymphangitis and tender axillary lymphadenopathy.

What is the most appropriate antibiotics therapy in this case?

- 1- Benzylpenicillin and flucloxacillin
- 2- Ceftriaxone
- 3- Ciprofloxacin
- 4- Co-amoxiclav
- 5- Erythromycin

Answer & Comments

Answer: 4- Co-amoxiclav

Only 15-20% of dog bites become infected, and providing the wound is appropriately cleaned and not considered at risk (for example, crush or deep wounds) then antibiotic prophylaxis may not be required.

However, this patient has an infected wound, and infective organisms include *Pasteurella* spp, *Staph. aureus* and anaerobes like *Corynebacterium*.

The most appropriate antibiotic therapy in dog bites associated with cellulitis would be co-amoxiclav.

[Q: 3894] OnExamination 2012 - Infectious disease

A 35-year-old man presented with cellulitis of his right leg.

On examination he was mildly confused and febrile (40.1°C) with a pulse of 120/minute and BP 80/55 mmHg.

He was treated with intravenous benzylpenicillin and flucloxacillin. Group A Streptococcus was isolated from two sets of blood cultures. There was no significant clinical improvement after 24 hours.

What antibiotic should be added?

- 1- Ciprofloxacin
- 2- Clindamycin
- 3- Gentamicin
- 4- Rifampicin
- 5- Vancomycin

Answer & Comments

Answer: 2- Clindamycin

The patient has a severe cellulitis with features of streptococcal toxic shock syndrome (TSS). Streptococcal TSS is mediated via streptococcal exotoxins.

Although clindamycin is a bacteriostatic antibiotic, it acts by switching off protein synthesis within bacteria; this in turn will lead to decreased exotoxin expression, thereby removing the mediators of TSS.

[Q: 3895] OnExamination 2012 - Infectious disease

A 43-year-old male presents with right iliac fossa pain and bloody diarrhoea for two days.

He had a fever, headache and myalgia the day before diarrhoeal illness. He is passing liquid bloody stools 10 times daily.

He has a history of HIV and is on HAART. His CD4 count has been well controlled, above 400 cells/μl.

What is the cause for his diarrhoea?

- 1- Appendicitis
- 2- Antiretroviral medication
- 3- Campylobacter
- 4- Cryptosporidium parvum
- 5- Cytomegalovirus

Answer & Comments

Answer: 3- Campylobacter

Campylobacter infection usually presents with bloody diarrhoea and 'pseudoappendicitis' (RIF pain). The patients often have a prodrome of fever, headache and myalgia. Campylobacter takes around seven to 10 days to incubate.

Both Cryptosporidium and Cytomegalovirus are found in patients with CD4 count less than 300 cells/μl. It causes chronic diarrhoea (more than four week's duration).

Patients commencing on antiretroviral medication may suffer with diarrhoea. It usually is self-limiting, lasting two to four weeks, and would not be associated with prodrome as in this case.

Given this gentleman's HIV status an infective cause for his diarrhoea is more likely than appendicitis.

[Q: 3896] OnExamination 2012 - Infectious disease

Which of the following is true of the the T cell response to antigen?

- 1- A process of affinity maturation of the T cell receptor occurs.
- 2- Intact antigen is presented in association with self MHC molecules.
- 3- Co-operation with other cell types is required for T cell recognition of antigen.

- 4- Gamma/delta + T cells respond to antigen presented in association with MHC class II molecules.
- 5- Interactions of the TcR with an appropriate Ag/MHC complex activates a resting T cell.

Answer & Comments

Answer: 3- Co-operation with other cell types is required for T cell recognition of antigen.

A. Affinity maturation in an ongoing immune response is a feature of the antibody response. There is no evidence that a similar process occurs in the T cell response.

B. Major histocompatibility complex (MHC) molecules present short antigen-derived peptides, not the intact antigen.

C. T cells recognise antigen only when presented by (self) MHC molecules on an antigen presenting cell.

D. MHC class II molecules present antigen to CD4+, alpha/beta+ T cells. It is still not clear how gamma/delta+ T cells recognise antigen, however most gamma/delta+ T cells do not appear to be restricted by (self) MHC molecules.

E. Additional 'costimulatory' signals are required to activate a resting T cell. Interaction of the T cell receptor (TcR) of a resting T cell with an appropriate Ag/MHC complex in the absence of costimulatory signals may lead to the induction of anergy.

[Q: 3897] OnExamination 2012 - Infectious disease

A 20-year-old woman presented with a solitary, crusted, thickened lesion on her face one month after returning from a holiday in Central America.

What is the most likely diagnosis?

- 1- Cutaneous anthrax
- 2- Cutaneous leishmaniasis

- 3- Impetigo
- 4- Leprosy
- 5- Onchocerciasis

Answer & Comments

Answer: 2- Cutaneous leishmaniasis

The patient has American ('New World') cutaneous leishmaniasis.

The causative agents are of the Leishmania species, including L. braziliensis, L. mexicana, L. panamensis and others.

The incubation period is very variable ranging from two weeks to several months.

A variety of clinical manifestations are described, including single or multiple lesions or mucosal disease (espundia). Lesions usually occur on sun-exposed areas.

Treatment is usually with pentavalent antimonial drugs.

[Q: 3898] OnExamination 2012 - Infectious disease

A 25-year-old male presents with fever, malaise and lethargy two weeks after visiting family in India.

A blood film for malaria parasites is reported as negative.

What is the next most appropriate investigation?

- 1- Blood culture
- 2- Chest x ray
- 3- Interferon gamma releasing assay (IGRA)
- 4- Urine culture
- 5- Widal test

Answer & Comments

Answer: 1- Blood culture

After malaria, enteric fevers are important to exclude.

Blood cultures are the most important investigation for enteric fevers caused by *Salmonella typhi* or *S. paratyphi*.

The Widal test, a demonstration of agglutinating antibodies against somatic O and flagella H antigen of *Salmonella* species is non-specific and, therefore, less reliable.

[Q: 3899] OnExamination 2012 - Infectious disease

A 17-year-old girl presents with three day history of vaginal discharge and pruritis.

What is the most likely causative organism?

- 1- Bacterial vaginosis
- 2- *Candida albicans*
- 3- *Chlamydia trachomatis*
- 4- *Neisseria gonorrhoeae*
- 5- *Trichomonas vaginalis*

Answer & Comments

Answer: 2- *Candida albicans*

There is very little information given in this girl's case, save for the three day history of vaginal discharge.

There is no information given with regard to pruritus, sexual exposure or whether the discharge is malodorous.

Without this information you must consider the most likely organism as a cause of a vaginal discharge with few other symptoms, which is *Candida*.

You may feel this question is unfair but it reflects the questions in the examination that are 'probability' based.

[Q: 3900] OnExamination 2012 - Infectious disease

A 72-year-old gentleman presents with increasing shortness of breath, fever and cough.

A chest x ray shows findings consistent with a right middle lobe pneumonia.

Which factor is associated with a worse prognosis?

- 1- Blood pressure of 120/80 mmHg
- 2- Respiratory rate of 18/min
- 3- Temperature of 37.2
- 4- Urea of 18 mmol/l
- 5- White cell count of 15×10^9

Answer & Comments

Answer: 4- Urea of 18 mmol/l

LBTS guidelines suggest

Increasing age

Co-morbidity

Respiratory rate above 30/min

BP less than 90 systolic

Hypoxaemia

WCC <4 or $>20 \times 10^9/L$ ($4-11 \times 10^9$)

Chest radiographic signs

Positive blood cultures

Confusion and

Urea above 7 mmol/l

are indicators of a worse prognosis associated with community acquired pneumonia.

[Q: 3901] OnExamination 2012 - Infectious disease

A 45-year-old woman was diagnosed with bacterial endocarditis.

What is the characteristic fundoscopic feature of this disease?

- 1- Cherry red macula
- 2- Janeway lesions
- 3- Macular star

4- Retinal artery aneurysms

5- Roth's spots

Answer & Comments

Answer: 5- Roth's spots

Roth's spots are the fundoscopic hallmark of bacterial endocarditis. They are white-centred retinal haemorrhages, caused by capillary fragility. In addition to subacute bacterial endocarditis, they can also be seen in leukaemia and retinal ischaemia.

Other peripheral features of endocarditis include Osler's nodes (tender subcutaneous nodules caused by immune complex deposition), and Janeway lesions (painless erythematous or haemorrhagic macular or papular lesions, on the palms and soles, caused by infective emboli in the skin).

A cherry-red spot on the macula is characteristic of central retinal artery occlusion. It is seen due to relative pallor of the surrounding retina.

A macular star is caused by deposits of hard exudate (usually lipid) within the fibre layer of the retina, radiating out in a star-like pattern. It can occur in a number of conditions, including hypertensive retinopathy and neuroretinitis.

Retinal artery aneurysms develop with age, and can be associated with hypertension. They are usually benign, but can result in macular haemorrhage, exudate or oedema, or vitreous haemorrhage.

[Q: 3902] OnExamination 2012 - Infectious disease

A 14-year-old boy presents with fever.

Which of the following might contribute to a diagnosis of rheumatic fever?

1- A CRP of 10

2- A prolonged PR interval on ECG

3- Finding target lesions on the hands

4- Finding tender nodules in the fingertips

5- Positive Romberg's sign

Answer & Comments

Answer: 2- A prolonged PR interval on ECG

The modified Jones criteria include:

Finding of preceding streptococcal infection (recent scarlet fever, raised ASOT or other streptococcal antibodies)

Positive throat swab for Group A Strep.

Plus:

(a) Major Criteria:

- Carditis
- Polyarthritides
- Chorea
- Subcutaneous nodules
- Erythema marginatum.

(b) Minor Criteria:

- Fever
- Arthralgia
- Previous history of rheumatic fever
- Elevated acute phase reactions
- Prolonged PR interval.

Erythema marginatum involves red circular lesions which gradually enlarge with central clearing.

Sydenham's chorea consists of choreoathetoid movements with increased clumsiness, for example, deteriorating handwriting. This is often associated with emotional lability.

Target lesions suggest erythema multiforme.

A C reactive protein (CRP) of 10 is not elevated much beyond the normal range.

Erythema marginatum initially manifests as non-specific pink macules seen over the trunk, with later blanching in the middle of the lesions and sometimes fusing of the borders resulting in a serpiginous (serpent-like) looking lesion. The rash is worsened with heat, but is characteristically evanescent. It does not itch, and can be mistaken for the rash of Lyme disease.

Sub-cutaneous nodules are pea-sized, firm and non-tender. There is no associated inflammation and they are characteristically seen on the extensor surfaces of joints such as knees and elbows and also over the spine.

[Q: 3903] OnExamination 2012 - Infectious disease

A 16-year-old boy from India presents with fever of four months duration and splenomegaly.

What is the most likely diagnosis?

- 1- Coccidioidomycosis
- 2- Giardiasis
- 3- Tropical sprue
- 4- Typhoid
- 5- Visceral leishmaniasis

Answer & Comments

Answer: 5- Visceral leishmaniasis

Visceral leishmaniasis (Kala-azar) is an endemic disease in several regions of India and sub-Saharan Africa. It is caused by the parasite *Leishmania donovani* and spread by *Phlebotomus* sand-flies.

Leishmaniasis is common in immune-suppressed patients, particularly those infected with HIV. There has recently been a substantial increase of cases in the Mediterranean region. It has been estimated that 15% of HIV positive drug users in Spain are infected with *Leishmania donovani* infantum.

Giardiasis and tropical sprue present with gastrointestinal symptoms and malabsorption.

Typhoid is an acute illness.

Coccidioidomycosis is largely confined to the Americas. Most patients present with pulmonary symptoms although disseminated disease can occur particularly in the immune-suppressed.

[Q: 3904] OnExamination 2012 - Infectious disease

Twenty of 30 patients in an adult ward develop colicky abdominal pain and diarrhoea without vomiting between 21:00 and 01:00 hrs.

Meat stew was served for lunch at noon.

Which of the following is the likely diagnosis?

- 1- *Bacillus cereus*
- 2- *Clostridium perfringens*
- 3- Enterotoxigenic *Escherichia coli*
- 4- Enterovirus
- 5- *Staphylococcus aureus*

Answer & Comments

Answer: 2- *Clostridium perfringens*

This food poisoning with no vomiting and an incubation period between 9-13 hours is typical of *Clostridium perfringens*.

The history is too long for a typical *Staph. aureus* infection (vomiting a typical feature, incubation period one to six hours) and rather short for enterovirus (24 hours).

B. cereus can cause two patterns of disease. The classic emetic form is caused by the ingestion of toxin and is characterised by nausea and vomiting, similar to *Staphylococcus aureus*. Rice products are generally the cause of this form.

The diarrhoeal form is caused by the ingestion of the organism, which releases toxin within

the stomach. This can produce an illness similar to *C. perfringens* with watery diarrhoea and abdominal cramps. Meats, milk, vegetables and fish have been associated with this form of the illness. This form is much less common, and the incubation period is classically shorter (1-6 hours) and therefore in this case *C. perfringens* is much more likely to be the diagnosis.

Escherichia coli infection has an incubation period of 12-24 hours and is also associated with marked vomiting.

Supportive treatment is all that is generally required with symptoms resolving after 24 hours.

[Q: 3905] OnExamination 2012 - Infectious disease

A 30-year-old renal transplant recipient presented with non-Hodgkin's lymphoma.

Which virus is most likely to be of aetiological significance?

- 1- Adenovirus
- 2- Cytomegalovirus
- 3- Epstein-Barr virus
- 4- Herpes simplex type 1
- 5- Varicella zoster

Answer & Comments

Answer: 3- Epstein-Barr virus

EBV-associated lymphoproliferative disease may occur in individuals with inherited or acquired immunodeficiency syndromes.

Approximately 1% of renal transplant recipients develop post-transplant lymphoproliferative disease (PTLD) in the first year following their transplant.

[Q: 3906] OnExamination 2012 - Infectious disease

A 27-year-old Somali female presents with a

two month history of weight loss, fever and night sweats.

Chest x ray reveals right upper lobe infiltrates. 3 x sputa are smear -ve.

What is the next most appropriate investigation?

- 1- Bronchoalveolar lavage (BAL)
- 2- CT scan of chest
- 3- HIV test
- 4- Interferon gamma releasing assay (IGRA)
- 5- Tuberculin skin test (TST)

Answer & Comments

Answer: 1- Bronchoalveolar lavage (BAL)

The history, clinical presentation and radiological findings are highly suggestive of pulmonary TB.

BAL is more sensitive than sputum collection at detecting TB, either by smear or culture.

In cases of suspected TB every effort should be made to confirm a suspected diagnosis by culture.

Susceptibility testing is important as detection of resistance alters the combination of drugs and duration of treatment.

[Q: 3907] OnExamination 2012 - Infectious disease

A 45-year-old man returned from a two week trip in Zimbabwe.

Fourteen days later he presented with fever, sore throat, headaches and a widespread maculopapular rash. On examination there was generalised lymphadenopathy and a widespread maculopapular rash.

What is the most likely diagnosis?

- 1- Acute HIV infection
- 2- Schistosomiasis
- 3- Strongyloidiasis

- 4- Tick typhus
- 5- Typhoid fever

Answer & Comments

Answer: 1- Acute HIV infection

It is essential to exclude acute human immunodeficiency virus (HIV) in this case. Acute retroviral syndrome is said to occur in 60-80% of patients between two and 12 weeks following exposure to HIV.

Typical symptoms include fever, pharyngitis, lymphadenopathy and a widespread macular rash. The illness closely resembles infectious mononucleosis.

During seroconversion it is likely that the HIV antibody test will be negative; the diagnosis is made by polymerase chain reaction (PCR) of peripheral blood for HIV ribonucleic acid (RNA); in acute HIV the viral load is very high.

"The time from exposure to onset of symptoms is usually 2-4 weeks, but the incubation may be as long as 10 months in rare cases (N Engl J Med 1998;339:33; N Engl J Med 1997;336:919).

Typical symptoms in a review of 209 cases (J Infect Dis 1994;168:1490) included fever (96%), adenopathy (74%), pharyngitis (70%), rash"

Kahn JO, Walker BD. Acute human immunodeficiency virus type 1 infection. N Engl J Med. 1998; 339(1):33-9. Review

[Q: 3908] OnExamination 2012 - Infectious disease

A 16-year-old boy presented with fever, headache and neck stiffness for 24 hours. He had an identical illness requiring admission to hospital for one year previously.

Cerebrospinal fluid analysis shows white cells of 400/ml with a 90% neutrophilia and Gram stain revealed scanty Gram-negative diplococci.

Which component of the immune system is likely to be defective?

- 1- B lymphocytes

- 2- Complement pathway
- 3- Immunoglobulin
- 4- Neutrophils
- 5- T lymphocytes

Answer & Comments

Answer: 2- Complement pathway

This young man has a recurrent meningococcal meningitis, and deficiencies of complement C5-9 predispose to Neisseria infections (complement deficiencies).

One must recognise that the diplococci seen on microscopy are those of Neisseria meningitidis.

[Q: 3909] OnExamination 2012 - Infectious disease

Which of the following is a cause of isolated B-cell immune deficiency?

- 1- Infection with measles
- 2- Multiple myeloma
- 3- Treatment with azathioprine
- 4- Treatment with corticosteroids
- 5- Treatment with cyclophosphamide

Answer & Comments

Answer: 2- Multiple myeloma

Excessive production of myeloma paraprotein is associated with progressive reduction in normal immunoglobulin levels and impairment of immune function.

Azathioprine, cyclophosphamide, corticosteroids and measles infection all cause reversible impairment of cell mediated immunity.

[Q: 3910] OnExamination 2012 - Infectious disease

A 19-year-old man presented with purulent

urethral discharge.

Microscopy of an urethral swab showed neutrophils but no organisms.

Which of the following antibiotics should be started?

- 1- Ciprofloxacin
- 2- Co-amoxiclav
- 3- Doxycycline
- 4- Metronidazole
- 5- Penicillin

Answer & Comments

Answer: 3- Doxycycline

The diagnosis is non-gonococcal urethritis (NGU). A presumptive diagnosis of gonococcal urethritis is made if Gram negative diplococci are seen within the neutrophils.

Doxycycline is the drug of choice for NGU. Alternative therapies include erythromycin, azithromycin, ofloxacin and ciprofloxacin.

Chlamydia trachomatis is the commonest cause of NGU accounting for 30-50% of cases.

All sexual partners at risk should be assessed and offered epidemiological treatment.

Guidelines:

British Association for Sexual Health and HIV

[Q: 3911] OnExamination 2012 - Infectious disease

A 30-year-old intravenous drug abuser develops acute aortic regurgitation due to infective endocarditis.

Which of the following is not typical of acute aortic regurgitation?

- 1- Decrescendo diastolic murmur
- 2- Hypotension
- 3- Mitral valve pre-closure
- 4- Normal cardiac output
- 5- Peripheral vasodilatation

Answer & Comments

Answer: 5- Peripheral vasodilatation

Findings that would be typical include:

Large pulse volume

Increased pulse pressure

A decrescendo murmur

A low diastolic blood pressure.

Vasoconstriction not dilatation is typically found.

[Q: 3912] OnExamination 2012 - Infectious disease

Which of the following is correct regarding human varicella zoster immunoglobulin (VZIG)?

- 1- Is invariably protective against severe varicella.
- 2- Is recommended for all patients with eczema exposed to chickenpox.
- 3- Is used to treat severe chicken pox infection
- 4- Should be given to a 6 week old baby whose mother has developed chickenpox
- 5- Should be given to an 18 week pregnant non-immune female who has been exposed to a case of chicken pox.

Answer & Comments

Answer: 5- Should be given to an 18 week pregnant non-immune female who has been exposed to a case of chicken pox.

Varicella has a secondary infection rate in household contacts of 90%. It is commonest in spring time, and the incubation period is 14-21 days. It shares the herpes virus family properties of latency and reactivation (zoster).

Risks to the fetus and neonate relate to the time of infection:

Less than 20 weeks pregnancy: congenital varicella (limb hypoplasia, microcephaly,

cataracts, growth retardation, skin scarring).
High mortality.

Second to third trimester: herpes zoster in an otherwise healthy infant.

Minus seven days to plus seven days after delivery: severe and even fatal disease (30% mortality).

Although a live attenuated vaccine is available, it is not licensed for use in the UK.

Varicella zoster immunoglobulin is prepared from pooled plasma of UK blood donors with a history of recent chickenpox or herpes zoster.

Being an immunoglobulin, it is a protein concentrate, and should be stored between 2 and 8°C. Donors are screened for HIV, hepatitis B and hepatitis C.

VZIG prophylaxis is recommended for patients who fulfil all the following criteria:

A clinical condition that increases the risk of severe varicella, (for example, immunosuppression, neonates, pregnant women)

No antibodies to varicella zoster

Significant exposure to chickenpox or herpes.

VZIG prophylaxis is of no benefit if chickenpox has already developed.

Severe or fatal varicella can occur despite VZIG prophylaxis. Active immunisation should therefore be used for susceptible immunosuppressed patients at long term risk.

Clinical chickenpox occurs in 50% of those who receive VZIG prophylaxis, and 10% more will be affected sub-clinically.

Green Book Varicella (PDF)

[Q: 3913] OnExamination 2012 - Infectious disease

Which of the following micro-organisms is generally sensitive to benzylpenicillin?

- 1- Bordetella pertussis
- 2- Cryptococcus neoformans
- 3- Legionella pneumophila
- 4- Mycoplasma pneumoniae
- 5- Streptococcus pneumoniae

Answer & Comments

Answer: 5- Streptococcus pneumoniae

Penicillin binds to specific penicillin-binding proteins (PBPs) in the cell wall, mainly of Gram positive organisms.

Penicillin resistance is usually due to production of altered PBPs, which reduce binding of penicillin, or beta-lactamases which cleave the beta lactam ring.

Penicillin is mainly useful for group A Strep., Group B Strep., meningococcal and pneumococcal infections, though anthrax are also sensitive.

Pneumococci with modified PBPs are an increasing problem.

[Q: 3914] OnExamination 2012 - Infectious disease

A 23-year-old aid worker returns from a spell working alongside locals in a river delta area of Thailand.

During his journey home he developed profuse watery diarrhoea with nausea and vomiting. He opened his bowels some 30 times during the flight. Despite the airline staff trying to give him regular fluids he faints on his arrival in the United Kingdom and is brought to the Emergency department.

On examination his BP is 130/70 mmHg, with a pulse of 90. He has a postural drop of 30 mmHg on standing. There is diffuse abdominal tenderness and very active bowel sounds.

Investigations show:

Hb 14.1 (13.0 - 18.0 g/dL)

WCC 11.2 ($4 - 11 \times 10^9/L$)
 PLT 395 ($150 - 400 \times 10^9/L$)
 Na 144 ($137 - 144 \text{ mmol/L}$)
 K 3.1 ($3.5 - 4.9 \text{ mmol/L}$)
 Cr 199 ($60 - 110 \mu\text{mol/l}$)
 Urea 15.1 ($2.5 - 7.5 \text{ mmol/L}$)

Which of the following is the most important initial therapy?

- 1- Ciprofloxacin
- 2- Doxycycline
- 3- Fluid resuscitation
- 4- Metronidazole
- 5- Penicillin

Answer & Comments

Answer: 3- Fluid resuscitation

This man has evidence of severe dehydration. The suspicion is that he may have cholera, the risk of which is increased according to length of stay in an endemic area, and exposure to poorly cooked / infected seafood.

Fluid resuscitation is the mainstay of therapy for the condition which can lead to severe dehydration as evidenced here by the marked elevation in creatinine and urea.

Antibiotics may play a role in shortening the duration of clinical symptoms and impacting on excretion of *Vibrio* but they are not the mainstay of treatment. Thus, all of the other options are incorrect.

In some cases of severe disease however, tetracyclines or quinolones may be considered.

[Q: 3915] OnExamination 2012 - Infectious disease

A 25-year-old male homosexual is admitted with dyspnoea and weight loss of two months duration.

He is diagnosed with *Pneumocystis pneumoniae* due to AIDS.

*Which of the following concerning *Pneumocystis pneumonia* is true?*

- 1- May have an extra pulmonary presentation
- 2- It is always associated with x ray changes
- 3- It is caused by a bacterium
- 4- Elevated serum antibodies to *P. carinii* are helpful diagnostically
- 5- It is best treated with intravenous pentamidine

Answer & Comments

Answer: 1- May have an extra pulmonary presentation

- A. As would any HIV associated condition.
- B. Five to 15% have normal CXR.
- C. It is caused by a fungus.
- D. There is polyclonal B-cell activation in AIDS.
- E. It is best treated with intravenous cotrimoxazole.

[Q: 3916] OnExamination 2012 - Infectious disease

*Which of the following is true of *Giardia lamblia* infection?*

- 1- Causes steatorrhea
- 2- Diagnosed by stool culture
- 3- Is eradicated by mebendazole
- 4- Is often symptomatic
- 5- Is usually spread by contaminated meats

Answer & Comments

Answer: 1- Causes steatorrhea

It is usually acquired by the faeco-oral route.

Many individuals excreting cysts are asymptomatic and are thus carriers. Others

have diarrhoea, steatorrhoea, abdominal pain and nausea.

It is diagnosed by stool microscopy - if negative, the parasite is found in duodenal aspirates or biopsy. Testing of serum antibodies against *G. lamblia* trophozoites is not useful in diagnosing current infection.

Eradicate with metronidazole (or quinacrine, tinidazole, ornidazole, furazolidone, paromomycin). Mebendazole is used in treating hookworm infections, for example, *Ascaris*, whipworm and threadworm.

[Q: 3917] OnExamination 2012 - Infectious disease

A 23-year-old male presented with a two week history of dysuria and purulent penile discharge. Gram stain of a urethral swab showed Gram negative intracellular diplococci.

Which one of the following is the most likely causative organism?

- 1- Chlamydia trachomatis
- 2- Cytomegalovirus
- 3- Mycoplasma hominis
- 4- Neisseria gonorrhoeae
- 5- Ureaplasma urealyticum

Answer & Comments

Answer: 4- Neisseria gonorrhoeae

Neisseria gonorrhoeae occurs in young adults and is often preceded by a migratory tendonitis or arthritis. Gram stain is positive in 25% and culture positive in 50%.

Neisseria gonorrhoeae is a species of Gram negative bacteria responsible for the disease gonorrhoea. They are highly fastidious Gram negative cocci, that is, they require special nutrients to survive. These cocci typically appear in pairs (diplococci).

[Q: 3918] OnExamination 2012 - Infectious disease

A 23-year-old woman presents 16 weeks into her pregnancy with a vaginal discharge.

Further investigation confirms infection with *Chlamydia trachomatis*.

Which of the following is the most appropriate treatment for this patient?

- 1- Ciprofloxacin
- 2- Co-trimoxazole
- 3- Doxycycline
- 4- Erythromycin
- 5- Metronidazole

Answer & Comments

Answer: 4- Erythromycin

C. trachomatis infection is common in pregnancy and is associated with adverse fetal outcome including:

Spontaneous miscarriage

Premature rupture of membranes and

Intrauterine growth retardation (IUGR).

Appropriate treatment is with macrolides such as erythromycin or azithromycin,

Erythromycin has an established safety profile in pregnancy whereas at present the BNF states that azithromycin should be used with caution.

Azithromycin is becoming more widely used as WHO guidelines now recommend its use as it has advantages over erythromycin such as a lower side effect profile and a single one-off dose treatment which results in increased compliance.

Local guidelines should be consulted. Of the options provided here, erythromycin is the most appropriate.

Both doxycycline and ciprofloxacin are contraindicated in pregnancy.

[Q: 3919] OnExamination 2012 - Infectious disease

An 18-year-old male presented with a two week history of dysuria and purulent penile discharge.

Gram stain of a urethral swab showed Gram negative intracellular diplococci.

What specific treatment should he receive?

- 1- Cefixime
- 2- Cephadrine
- 3- Ciprofloxacin
- 4- Co-amoxiclav
- 5- Crystalline penicillin

Answer & Comments

Answer: 1- Cefixime

Neisseria gonorrhoeae occurs in young adults and is often preceded by a migratory tendonitis or arthritis.

Gram stain is positive in 25% and culture positive in 50%.

Current UK guidelines recommend first line treatment with either cefotaxime, cefixime or spectinomycin may be given (as a stat dose).

Fluoroquinolones are no longer used as first line treatment due to the high rate of resistance.

[Q: 3920] OnExamination 2012 - Infectious disease

One of the nurses working on the care of the elderly ward sustains a needlestick injury while taking blood from a patient.

What is the most appropriate immediate management?

- 1- Administer prophylactic hepatitis B immunoglobulin (HBIG) regardless of vaccine status
- 2- Exclude the nurse from performing exposure-prone procedures for three

months until a negative HIV antibody test has been obtained

- 3- Immediately take the nurse's blood to test for antibodies to hepatitis B, hepatitis C and human immunodeficiency viruses
- 4- Prompt administration of antiretroviral therapy
- 5- Wash the wound with soap under running water

Answer & Comments

Answer: 5- Wash the wound with soap under running water

The first line of management of needlestick injuries includes immediate washing under running water.

All incidents should be reported to the occupational health department and have a careful risk assessment.

HBIG is given only if the donor is known to be hepatitis B positive and the victim is non-immune.

Antiretroviral therapy is given, after counselling, if the donor is known HIV positive and the exposure is deemed high risk.

[Q: 3921] OnExamination 2012 - Infectious disease

A 19-year-old male student attends the Emergency department complaining of an urethral discharge one week after having casual unprotected sex.

Gram stain shows numerous neutrophils, some of which contain Gram negative intracellular diplococci. The patient is treated with ceftriaxone 250 mg as an intramuscular injection. Five days later, the patient re-attends with persisting discharge.

Which of the following is the most likely cause of this discharge?

- 1- Chlamydia trachomatis

- 2- Penicillin-resistant *Neisseria gonorrhoeae*
- 3- Re-infection with *Neisseria gonorrhoeae*
- 4- *Ureaplasma urealyticum*
- 5- Urethral stricture

Answer & Comments

Answer: 1- *Chlamydia trachomatis*

This patient has been adequately treated for gonorrhoea and a persistent discharge would be unusual unless, as is often the case, there is a co-infection.

The patient is likely to have a non-specific urethritis due to *Chlamydia trachomatis*, requiring treatment with either doxycycline or erythromycin for seven to 14 days.

[Q: 3922] OnExamination 2012 - Infectious disease

In the diagnosis of rheumatic fever, which of the following may be helpful?

- 1- A generalised macular-papular rash
- 2- ASO titre of less than 1:200
- 3- Polyarthrititis
- 4- Splinter haemorrhages
- 5- *Staphylococcus aureus* grown on throat culture

Answer & Comments

Answer: 3- Polyarthrititis

Of the following Jones criteria, two major, or one major and two minor, and evidence of recent streptococcal infection, is required for the diagnosis of rheumatic fever (RF).

Major:

Pancarditis

Polyarthrititis

Erythema marginatum

Chorea

Subcutaneous nodules

The rash is macular.

Minor:

Fever

Polyarthralgia

History of RF

Raised erythrocyte sedimentation rate/c-reactive protein (ESR/CRP)

Prolonged PR interval on electrocardiogram (ECG).

[Q: 3923] OnExamination 2012 - Infectious disease

A 52-year-old woman was admitted with malaise and leg weakness.

Her illness started with a sore throat while travelling in eastern Europe.

On examination she was febrile (39.1°C) with several areas of exudates on her pharynx and extensive cervical lymphadenopathy. There was weakness of the legs with absent tendon reflexes.

What is the most likely diagnosis?

- 1- Acute myeloid leukaemia
- 2- Cytomegalovirus infection
- 3- Diphtheria
- 4- Glandular fever
- 5- Streptococcal tonsillitis

Answer & Comments

Answer: 3- Diphtheria

This history of severe exudative pharyngitis in a person who has recently travelled to eastern Europe is highly suggestive of diphtheria.

The disease, caused by *Corynebacterium diphtheriae*, causes a severe pharyngitis with extensive soft tissue swelling and

lymphadenitis that produces a characteristic 'bull neck' appearance.

Exotoxins produced by the organism may cause myocarditis or neurological defects. The degree of neurological toxicity varies, but may be severe, causing cranial neuropathies, predominantly motor peripheral neuropathy (occasionally sensory neuropathy).

An epidemic of diphtheria began in Russia in the early 1990s and remains a significant public health problem in Russia and in the former Soviet states.

[Q: 3924] OnExamination 2012 - Infectious disease

A 18-year-old homosexual male developed progressive pneumonia not responding to antibiotics.

Methenamine silver staining of the sputum showed small circular cyst and Giemsa staining demonstrated the small, punctate nuclei of the trophozoites and intracystic sporozoite.

Which is the most likely organism?

- 1- Cryptococcus neoformans
- 2- Leishmania donovani
- 3- Pneumocystis carinii
- 4- Toxoplasma gondii
- 5- Trypanosoma cruzi

Answer & Comments

Answer: 3- Pneumocystis carinii

The organism is Pneumocystis carinii.

The organism may be identified on microscopy after

Methenamine silver staining for the cyst phase of the organism

Giemsa staining that demonstrates the small, punctate nuclei of the trophozoites and intracystic sporozoites; or

Fluorescence-tagged monoclonal antibody.

[Q: 3925] OnExamination 2012 - Infectious disease

A 25-year-old female recently returned from Nigeria, presents to the Emergency department with a two day history of fever and rigors.

Subsequently she develops a seizure.

What is the next most appropriate immediate investigation?

- 1- Blood culture
- 2- Blood film for malarial parasites
- 3- CT scan of head
- 4- Lumbar puncture
- 5- MR scan of head

Answer & Comments

Answer: 2- Blood film for malarial parasites

With a recent history of travel to Nigeria, cerebral malaria caused by *P. falciparum* should be considered as a likely cause of her symptoms.

Therefore, a malaria blood film should be performed.

Other investigations may be required but investigations for malaria should be performed immediately.

[Q: 3926] OnExamination 2012 - Infectious disease

Which of the following is true regarding varicella zoster infection?

- 1- Associated pneumonitis is equally common in smokers and non-smokers
- 2- Causes congenital limb deformity
- 3- Causes urinary incontinence
- 4- Gamma interferon is an effective treatment.

- 5- Produces latent infection within the anterior horn cells

Answer & Comments

Answer: 2- Causes congenital limb deformity

Varicella zoster infection causes herpes zoster and chicken pox.

Herpes zoster is due to reactivation of the virus lying dormant in the cells of dorsal root ganglion.

Autonomic involvement can cause urinary retention.

Pregnancy increases risk of pneumonitis.

Chicken pox in the first and second trimester can produce a syndrome of skin scarring, hypoplastic limbs, eye and central nervous system impairments.

Pneumonitis is uncommon in children with incidence of 0.3% in immunocompetent adults. The risk is higher in smokers.

Antiviral treatment includes aciclovir and vidabarine.

[Q: 3927] OnExamination 2012 - Infectious disease

Two strains of Escherichia coli are isolated and both are resistant to ampicillin.

Strain A retains its resistance to ampicillin when grown from multiple generations in the absence of ampicillin.

However strain B loses its resistance when grown in the absence of ampicillin.

Which of the following best explains the loss of antibiotic resistance in strain B?

- 1- Changes in the bacterial DNA gyrase
- 2- Downregulation of the resistance gene
- 3- Loss of a plasmid containing the resistance gene
- 4- Mutations in the resistance gene

- 5- Transposition of another sequence into the resistance gene

Answer & Comments

Answer: 3- Loss of a plasmid containing the resistance gene

Bacteria develop resistance to antibiotics by gaining genes that encode particular proteins that offer protection to the organism.

Sometimes this is by mutation and other times the gene may be acquired from another bacterial species.

The genes are usually found in plasmids - circular segments of DNA separate from the bacterial chromosome.

Plasmids can easily spread from one bacteria to another - a sort of resistance package that bacteria can share.

[Q: 3928] OnExamination 2012 - Infectious disease

A 29-year-old man from Southampton with human immunodeficiency virus (HIV) infection (CD4 cell count 150 cells/mm³) is admitted to hospital with a 10 day history of fever (temperature 38.8°C), a dry cough, weight loss and night sweats.

There is a history of previous tuberculosis. His current medications include TDF/3TC/EFV and inhaled pentamidine.

Physical examination reveals crackles in the upper lung fields. Chest radiography reveals bilateral upper lobe infiltrates.

Initial results of his induced sputum examination demonstrate no organisms seen on Gram, fungal, acid-fast and Pneumocystis jiroveci pneumonia staining.

Which regimen would be most effective against the likely cause of this man's symptoms?

- 1- Clarithromycin and Amoxil

- 2- Ganciclovir
- 3- Isoniazid, rifampin, ethambutol and pyrazinamide
- 4- Itraconazole
- 5- Trimethoprim-sulfamethoxazole

Answer & Comments

Answer: 5- Trimethoprim-sulfamethoxazole

The clinical presentation of the said patient is compatible with *Pneumocystis jiroveci* pneumonia (PCP).

Inhaled pentamidine is not as effective as trimethoprim-sulfamethoxazole in preventing PCP.

Focal lobe infiltrates are more common in patients who have been receiving aerosol pentamidine prophylaxis. The sensitivity of induced sputum for PCP might be decreased in patients receiving pentamidine prophylaxis.

This patient requires bronchoscopy with bronchoalveolar lavage for diagnosis; trimethoprim-sulfamethoxazole is the treatment of choice unless the patient is allergic.

Isoniazid, rifampin, ethambutol and pyrazinamide are used in the treatment of tuberculosis.

Itraconazole is the wrong answer.

Pneumocystis jiroveci pneumonia is officially classified as fungal pneumonia, but lacks ergosterol and is not susceptible to antifungal drugs that inhibit ergosterol synthesis.

Ganciclovir is the treatment of choice for cytomegalovirus (CMV) infections. CMV is a differential diagnosis for PCP. It also presents with fevers, dyspnoea, and cough as the symptoms.

Clarithromycin and Amoxil are the empiric treatment for community acquired pneumonias caused by bacteria.

[Q: 3929] OnExamination 2012 - Infectious disease

You are asked to be part of a team reviewing the passengers on a cruise ship. Over the course of the past four days there has been a massive increase in cases of diarrhoea and vomiting and the ship has returned to port.

Currently over 300 passengers are estimated to be unwell. Apparently a number of passengers ate at the speciality seafood restaurant or are sharing cabins with passengers who did. Out of 10 passengers admitted to the local hospital so far, all of them showed signs of dehydration, but no signs of raised white cell count.

Which of the following is the most likely infective agent?

- 1- *Campylobacter*
- 2- Norovirus
- 3- Rotavirus
- 4- *Salmonella*
- 5-

Answer & Comments

Answer: 2- Norovirus

Three factors stand out:

The rapid spread of the diarrhoea and vomiting

The fact that most of the passengers had eaten in the ship's seafood restaurant

Patients admitted to the hospital so far show no signs of neutrophilia, but do show signs of dehydration.

Norovirus is concentrated in shellfish, small oysters and plankton, and person to person spread can occur from aerosols of projectile vomit or faecal material.

Rotavirus, in contrast, occurs more frequently in and is more severe in the paediatric population.

[Q: 3930] OnExamination 2012 - Infectious disease

A 35-year-old HIV positive African woman presented with weakness of both legs and double incontinence.

CSF showed increased protein and neutrophils with normal glucose.

What is the most likely cause of her weakness?

- 1- CMV polyradiculomyelopathy
- 2- Guillain-Barré syndrome
- 3- Herpes virus encephalitis
- 4- HIV encephalopathy
- 5- Toxoplasma encephalitis

Answer & Comments

Answer: 1- CMV polyradiculomyelopathy

Symptoms are suggestive of polyradiculomyelopathy (weakness of legs with involvement of sphincters).

Increased neutrophils are found in CMV polyradiculomyelopathy but not in Guillain-Barré syndrome.

HIV encephalopathy usually causes confusion and memory loss. It does not involve sphincters.

Guillain-Barré syndrome causes polyradiculopathy, explaining all her symptoms, but with normal cell counts and raised protein in the CSF.

Herpes simplex encephalitis causes fever, headache, confusion and deteriorating level of consciousness.

[Q: 3931] OnExamination 2012 - Infectious disease

Deficiency of which of the following components of the complement system predisposes to infection with Neisseria meningitidis?

- 1- C1q

2- C1r

3- C1s

4- C3

5- C4

Answer & Comments

Answer: 4- C3

The complement system often gives rise to questions in the MRCP examination. It would be wise to make a cursory review of this topic.

C3 is the point at which the classical, alternative and lectin complement pathways converge.

C1qrs, C2 and C4 are strongly associated with systemic lupus erythematosus (SLE).

Patients with C3 deficiency, be it absolute, relative, genetically determined (autosomal dominant or recessive) or due to properdin deficiency, are predisposed to recurrent infection with encapsulated proteins, particularly *N. meningitidis*.

C5 deficiency is associated with Leiner's disease, a syndrome of recurrent diarrhoea, wasting and generalised seborrhoeic dermatitis presenting in infants.

[Q: 3932] OnExamination 2012 - Infectious disease

A 30-year-old schoolteacher is admitted with headache, photophobia and neck stiffness.

His temperature is 39.0°C, pulse rate 120 beats/min and he has no skin rash or focal neurological signs. His Glasgow coma scale is 15/15.

A CT scan shows no contraindication to lumbar puncture. CSF is obtained and Gram stain shows Gram positive cocci, subsequent culture confirms a pneumococcal meningitis.

What chemoprophylaxis should be offered to his pupils?

- 1- Azithromycin

- 2- Ceftriaxone
- 3- Ciprofloxacin
- 4- No chemoprophylaxis required
- 5- Rifampicin

Answer & Comments

Answer: 4- No chemoprophylaxis required

Chemoprophylaxis is not normally indicated for close contacts of those with pneumococcal meningitis.

Chemoprophylaxis with rifampicin, ceftriaxone, ciprofloxacin or azithromycin is used for meningococcal meningitis.

Close contacts of *Haemophilus influenzae* meningitis should receive rifampicin; children under 2 years should be vaccinated.

[Q: 3933] OnExamination 2012 - Infectious disease

A 35-year-old man is seen six months after a cadaveric renal allograft. He receives azathioprine and prednisolone. He has felt generally unwell for the past week with a pyrexia of 38.6°C, anorexia and a cough productive of thick green sputum.

Chest x ray reveals a left lower lobe nodule of approximately 5 cm diameter with central cavitation. Analysis of the sputum reveals long, crooked, branching and beaded Gram positive filaments.

Which of the following antimicrobials is the most appropriate initial therapy for this patient?

- 1- Ceftazidime
- 2- Co-amoxiclav
- 3- Co-trimoxazole
- 4- Erythromycin
- 5- Rifampicin and isoniazid

Answer & Comments

Answer: 3- Co-trimoxazole

The likely diagnosis is nocardiosis.

Nocardia are aerobic, Gram positive branching filamentous bacteria which often appear beaded on staining. Nocardiosis can be diagnosed rapidly by examination of sputum or pus with the Gram stain and a modified acid-fast stain.

Pneumonia is typically found in the immunocompromised, as in this case and may be a single lesion or extensive pneumonic consolidation.

The drug of choice is trimethoprim-sulfamethoxazole.

[Q: 3934] OnExamination 2012 - Infectious disease

Regarding diphtheria which of the following statements is correct?

- 1- About 50 cases per year are seen in the UK.
- 2- It is characterised by an inflammatory exudate forming a greyish membrane on the buccal mucosa.
- 3- It is predominantly spread from cutaneous lesions.
- 4- It produces a toxin which affects the myocardium, nervous and adrenal tissues.
- 5- 3 doses of toxoid provides 75% protection.

Answer & Comments

Answer: 4- It produces a toxin which affects the myocardium, nervous and adrenal tissues.

Diphtheria is spread by droplets, through contact with soiled articles (fomites), and, in areas of poor hygiene, from cutaneous spread.

The inflammatory exudate forms a greyish membrane on the tonsils and respiratory tract which may cause respiratory obstruction.

Incubation is between two and five days, and patients may be infectious for four weeks.

The toxin affects the myocardium, nervous and adrenal tissues.

The immunisation has been tremendously successful, and most cases seen in the United Kingdom are imported from the Indian subcontinent or Africa.

Recently, there has been a worrying epidemic of diphtheria in Russia and the newly independent states of the former Soviet Union. In 1995, 52,000 cases and 1,700 deaths were reported.

[Q: 3935] OnExamination 2012 - Infectious disease

Which of the following is true of Koplik's spots?

- 1- Are diagnostic of measles
- 2- Located opposite the incisor teeth.
- 3- Only appear when fever is over 39°C
- 4- They appear as red papules on the palmar surface of the hands
- 5- Typically appear two days after the rash.

Answer & Comments

Answer: 1- Are diagnostic of measles

Koplik's spots are small, irregular, bright red spots with blue-white centres, occurring on the inside of the cheek next to the premolars.

Seen only in measles, they are diagnostic.

The spots usually occur briefly after the fever begins and a couple of days before the generalised rash appears.

Not infrequently, the spots disappear as the eruption develops.

[Q: 3936] OnExamination 2012 - Infectious disease

A 47-year-old Portuguese former intravenous drug abuser presented with a two week history of right hemiparesis.

He was found to have hepatitis B and C infection. His absolute lymphocyte count was 0.6×10^9 . CT of the head showed multiple ring-enhanced lesions.

What would be your next best course of action?

- 1- Manage him conservatively with physiotherapy
- 2- Refer him to a neurosurgeon for urgent brain biopsy
- 3- Refer him to a stroke specialist
- 4- Request an HIV antibody test
- 5- Start thrombolysis treatment

Answer & Comments

Answer: 4- Request an HIV antibody test

This man was already infected with two blood-borne viruses (hepatitis B and C). His absolute lymphocyte count was low. CT scan showed multiple ring-enhanced lesions, which were suggestive of cerebral toxoplasmosis.

Therefore, testing HIV is the next best course of action. Finding multiple ring-enhanced lesions on CT scan needs further investigations.

Managing conservatively with physiotherapy is not an appropriate course of action.

CT scan is not typical of brain tumour, hence referring him for urgent brain biopsy is not the best course of action.

Thrombolysis treatment should not be started, as the CT scan was not typical of ischaemic stroke.

Reference:

Yoganathan K. A brain tumour in an intravenous drug abuser. Accepted for publication in

International Journal of General Medicine in February 2009.

[Q: 3937] OnExamination 2012 - Infectious disease

Four members of a football team develop diarrhoea due to Salmonella enteritidis.

Eating which food was the most likely source of the infection?

- 1- Chicken at a fast food outlet 20 hours earlier
- 2- Fried rice at a takeaway 4 hours earlier
- 3- Raw eggs in milk 6 hours earlier
- 4- Raw oysters at a hotel 24 hours earlier
- 5- Soft cheeses 48 hours earlier

Answer & Comments

Answer: 1- Chicken at a fast food outlet 20 hours earlier

The incubation time for Salmonella enteritidis is 12-48 hours and the likely sources are poultry and eggs.

Raw oysters are associated with infections such as the Norwalk agent.

[Q: 3938] OnExamination 2012 - Infectious disease

Reverse transcriptase-PCR is used to amplify which of the following?

- 1- Antibodies
- 2- DNA
- 3- Plasmids
- 4- Protein
- 5- RNA

Answer & Comments

Answer: 5- RNA

Reverse transcriptase PCR is a means of amplifying ribonucleic acid (RNA).

The RNA is transcribed into complementary deoxyribonucleic acid (cDNA).

Using the enzyme reverse transcriptase, the cDNA is then amplified by conventional polymerase chain reaction (PCR).

[Q: 3939] OnExamination 2012 - Infectious disease

A 28-year-old woman comes to the clinic complaining of a thin fishy smelling discharge. She does not however have any vaginal irritation, redness or itching.

Despite using body wash and showering twice per day, she says the smell and discharge persists. She is in a stable relationship with her husband and has two young children.

Which of the following is the most likely diagnosis?

- 1- Bacterial vaginosis
- 2- C. trachomatis
- 3- Herpes simplex infection
- 4- N. gonorrhoeae
- 5- T. vaginalis

Answer & Comments

Answer: 1- Bacterial vaginosis

The answer is A, bacterial vaginosis.

This woman is in a stable relationship, with a history of excess body washing, the history of clear discharge without irritation fits best with bacterial vaginosis. It typically features a reduction in the number of the normal hydrogen peroxide-producing Lactobacilli in the vagina.

Simple measures such as reducing the use of body wash and considering using a lactic acid preparation to restore her natural vaginal flora will often reduce symptoms.

A course of oral metronidazole for five - seven days will further reduce discharge and odour.

In pregnancy, bacterial vaginosis may increase the risk of miscarriage.

[Q: 3940] OnExamination 2012 - Infectious disease

A 42-year-old single man comes to the clinic some two weeks after a tour to Thailand.

During his trip he admits to unprotected sex with a number of prostitutes. Since his return he has been suffering fevers and night sweats over the past few days and has noticed some swollen lymph nodes in his neck, arm pits and groin. He has also felt nauseous and been off his food.

On examination you confirm that he has a low-grade fever of 37.60C, and lymphadenopathy. He also has pharyngitis.

Investigations:

Haemoglobin 12.9 g/dl(13.5-17.7)

White cell count $9.8 \times 10^9/l$ (4-11)

Platelets $272 \times 10^9/l$ (150-400)

Serum Sodium 138 mmol/l (135-146)

Serum Potassium 4.0 mmol/l (3.5-5)

Creatinine 80 micromol/l (79-118)

Alanine aminotransferase 129 U/l (5-40)

You are wondering about acute HIV infection.

Which of the following would be an appropriate test to detect this?

- 1- Anti-HIV antibody by ELISA
- 2- Anti-HIV antibody by western blot
- 3- CD4 count
- 4- CD8 count
- 5- P24 antigen

Answer & Comments

Answer: 5- P24 antigen

The answer is E, P24 antigen.

The concern here is that testing would be too soon to detect antibodies to HIV in the serum.

As such P24 antigen testing may detect HIV infection one to three weeks after the event and is the most appropriate option here.

The alternative is HIV RNA testing to estimate viral load.

HIV antibody testing by western blot has a lower false positive rate than HIV antibody by ELISA and may be an option when a false positive result is suspected.

CD4 counts begin to reduce later in HIV infection.

[Q: 3941] OnExamination 2012 - Infectious disease

A 22-year-old student presents to the clinic complaining of a large crop of intensely painful blisters/ulcers and tingling pain affecting her vulva. She gives a history of unprotected sex on two occasions in the past two weeks, with a new partner who she met at a party.

She feels under the weather, is experiencing dysuria and has noticed vaginal discharge.

On examination you notice a number of small blisters/ ulcers over her vulva and tender inguinal lymph nodes.

Which of the following is the most likely diagnosis?

- 1- Bechet's syndrome
- 2- Chancroid
- 3- Genital herpes simplex
- 4- Genital herpes zoster
- 5- Syphilis

Answer & Comments

Answer: 3- Genital herpes simplex

The answer is C, genital herpes simplex.

The history of a mild constitutional illness coupled with painful and blistering genital ulceration and neuropathic type pain fits best

with herpes simplex infection. Viral swabs for PCR are used for confirming the diagnosis, and the patient should be started on an appropriate oral anti-viral such as aciclovir.

It is also mandatory that they undergo a full sexual health screen at the local genitourinary medicine clinic to exclude co-infection with another sexually transmitted disease.

Topical anti-virals have no value in the management of the condition. The ulcers of syphilis, a differential here, are usually painless.

[Q: 3942] OnExamination 2012 - Infectious disease

A 16-year-old boy is to be admitted to the hospital for elective splenectomy.

Which of the following booking times before surgery should he be given to receive his pneumococcal vaccination?

- 1- Three days
- 2- One week
- 3- Four weeks
- 4- Two months
- 5- Three months

Answer & Comments

Answer: 3- Four weeks

Patients should be vaccinated with an appropriate pneumococcal vaccination at least two weeks prior to surgery to allow the maximal humoral immune response. If they have not received the Haemophilus influenzae or meningococcal vaccinations, then they should also receive these.

In cases of emergency splenectomy related to trauma, patients should be vaccinated as early as possible after surgery. Patients who have undergone splenectomy are at significantly increased risk of infection from all three of these bacteria without vaccination.

They should also be enrolled in the yearly seasonal flu vaccination programme post splenectomy.

Reference:

Update of guidelines for the prevention and treatment of infection in patients with an absent or dysfunctional spleen (pdf) British Committee for Standards in Haematology

[Q: 3943] OnExamination 2012 - Infectious disease

A 72-year-old woman presents to her GP a few days after discharge from hospital after a community acquired pneumonia with some cellulitis around an old IV site on her left hand.

On examination she is pyrexial at 37.6°C, and has a 5 cm x 3 cm area of erythema and some discharging pus from the entry site of the needle.

Investigations show

Haemoglobin 11.6 g/dl (11.5-16.5)

White cell count $11.2 \times 10^9/L$ (4-11)

Platelets $193 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

Swab from cellulitis site MRSA

Which of the following is the most appropriate empirical antibiotic for her whilst awaiting sensitivities?

- 1- Co-trimoxazole
- 2- Doxycycline
- 3- Flucloxacillin
- 4- Trimethoprim
- 5- Vancomycin

Answer & Comments

Answer: 2- Doxycycline

This woman has an area of methicillin-resistant Staphylococcus aureus (MRSA)

cellulitis on her hand which is likely to respond to oral antibiotic therapy; her white count and temperature are only mildly elevated.

Tetracyclines and clindamycin are known to have activity against MRSA and can be delivered orally; as such, either option would be a reasonable empirical choice in this case.

For more severe infections, either IV vancomycin or linezolid may be an appropriate option.

[Q: 3944] OnExamination 2012 - Infectious disease

A 34-year-old Thai lady presented with a left hemiparesis of two weeks duration.

HIV antibody test was positive. CT scan of the head showed multiple ring-enhanced lesions.

What is the most likely cause of her weakness?

- 1- Amoebic brain abscesses
- 2- Cerebral toxoplasmosis
- 3- Herpes simplex encephalitis
- 4- Primary brain lymphoma
- 5- Progressive multifocal leucoencephalopathy

Answer & Comments

Answer: 2- Cerebral toxoplasmosis

Cerebral toxoplasmosis is the most likely diagnosis. Multiple ring-enhanced lesions are commonly seen in patients with cerebral toxoplasmosis, though solitary ring enhanced lesions are seen in 25% of patients on CT scan. MRI scan is more sensitive in identifying small lesions than CT scan.

Amoebic brain abscesses are not the most likely cause in this patient.

Multiple ring-enhanced lesions are not seen in patients with herpes simplex encephalitis.

Primary brain lymphoma causes a significant mass effect with surrounding oedema.

Progressive multifocal leucoencephalopathy causes multifocal white matter lesions without any mass effect or surrounding oedema.

Reference:

Yoganathan K., A brain tumour in an intravenous drug abuser. Accepted for publication in International Journal of General Medicine, February 2009.

[Q: 3945] OnExamination 2012 - Infectious disease

Which of the following is correct concerning oseltamivir?

- 1- It is a direct viral cytotoxic agent
- 2- It is a haemagglutinin inhibitor
- 3- It is administered via an inhaler
- 4- It is effective if administered within 72 hours of symptoms of flu
- 5- It is of value in prophylaxis against influenza

Answer & Comments

Answer: 5- It is of value in prophylaxis against influenza

Oseltamivir (Tamiflu), like its predecessor zanamivir (Relenza) functions as an antiviral through inhibition of the enzyme neuraminidase, thus slowing viral replication down rather than directly killing the virus particle.

This slowing down of replication is important in permitting time for the body's own immune system to deal with the virus.

Unlike inhaled zanamivir, oseltamivir is administered orally.

However, viral replication is rapid and to be effective the drug must be given as early as possible after the development of symptoms of flu and preferably within 48 hours.

[Q: 3946] OnExamination 2012 - Infectious disease

Which one of the following measures would be most effective in reducing transmission of E coli O157:H7 during an outbreak of diarrhoea caused by this organism?

- 1- Drinking only boiled water
- 2- Ensuring that meat products are thoroughly cooked
- 3- Giving antibiotics to individuals who are positive for E. coli on stool culture
- 4- Hand washing before preparing food
- 5- Isolation of individuals with diarrhoea

Answer & Comments

Answer: 2- Ensuring that meat products are thoroughly cooked

Cattle are a major reservoir of Escherichia coli O157:H7 and contaminated meat is the most commonly implicated source of outbreaks.

Raw meat should be separated from cooked and ready-to-eat food. Hands should be washed after handling raw meat.

Antibiotics are not routinely indicated and patients should be educated on personal hygiene.

[Q: 3947] OnExamination 2012 - Infectious disease

An 35-year-old man presented with high fever, headache and mild jaundice on returning from a holiday in Spain. The group of 20 had travelled together visiting forestry on the hills with fishing trips in mountain streams.

Which of the following organisms is most likely to be responsible for his illness?

- 1- Borrelia burgdorferi
- 2- Legionella pneumophila
- 3- Leptospira icterohaemorrhagiae
- 4- Mycoplasma pneumoniae

5- Pneumococcus

Answer & Comments

Answer: 3- Leptospira icterohaemorrhagiae

Leptospirosis, or Weil's disease, is transmitted to man by animals, including rodents (rat urine and faeces), skunks, foxes, cattle, dogs.

The disease is characterised by

- Jaundice
- Fever
- Oliguria
- Headache
- Myalgia
- Haemorrhagic tendencies with purpura or petechiae
- Enlargement of liver and spleen.

[Q: 3948] OnExamination 2012 - Infectious disease

One of the surgical wards in your hospital notes an outbreak of methicillin-resistant Staphylococcus aureus (MRSA) infections.

What is the best mechanism for reducing further transmission of this infection?

- 1- Cleaning the floors and walls of the ward with chlorhexidine
- 2- Close the ward for one month
- 3- Encourage regular hand washing by ward staff
- 4- Screen ward staff using nasal swabs and exclude those with positive cultures for MRSA
- 5- Treatment of culture-positive patients with vancomycin

Answer & Comments

Answer: 3- Encourage regular hand washing by ward staff

Cross-infection via hands of medical and nursing staff is a very important vehicle of transmission of MRSA.

Hand washing before and after contact with patients is the single most effective measure to control hospital spread of this organism.

Screening of ward staff is appropriate only in certain situations and should not be carried out unless recommended by the hospital infection control team.

Vancomycin should never be used for MRSA decolonisation.

The hospital infection control policy should outline which patients should be screened and when decolonisation should be attempted.

[Q: 3949] OnExamination 2012 - Infectious disease

Which of the following is a contraindication to immunisation?

- 1- A child with cerebral palsy.
- 2- A child with congenital adrenal hyperplasia on oral cortisone.
- 3- A history of prolonged jaundice.
- 4- Infantile eczema requiring topical steroids.
- 5- Oral poliomyelitis vaccine to a child on oral steroids.

Answer & Comments

Answer: 5- Oral poliomyelitis vaccine to a child on oral steroids.

Common misconceptions regarding immunisations include that vaccinations cannot be given to the following patient groups:

A family history of adverse reaction, or a previous history of pertussis, measles, rubella or mumps infection

Prematurity or low birth weight

Stable neurological conditions such as cerebral palsy or Down's syndrome

Asthma, eczema, hayfever or snuffles

Contact with an infectious disease, or treatment with antibiotics or topical steroids

Pregnant mother or a mother who is breast feeding

Prolonged jaundice

Patients on replacement corticosteroids.

In general, it is safe to give all these patients vaccinations but in most cases it is discussed with a specialist (or there are specific guidelines). However, the oral polio vaccine (which is live) should not be given to immunosuppressed children, their siblings or household contacts. Live vaccines are also usually not given to pregnant women.

In children with HIV, there is little evidence that they themselves will have problems, but excretion may be prolonged, and this may give rise to an increased risk of infection of HIV positive household contacts.

[Q: 3950] OnExamination 2012 - Infectious disease

A 51-year-old homosexual Caucasian HIV positive man developed multiple violaceous painless lesions on his trunk.

Which one of the following is the most likely cause of his skin lesions?

- 1- Cytomegalovirus (CMV)
- 2- Human herpes virus 8 (HHV8)
- 3- Human herpes virus 10 (HHV 10)
- 4- Human papilloma virus 16 (HPV 16)
- 5- Pox virus

Answer & Comments

Answer: 2- Human herpes virus 8 (HHV8)

Multiple violaceous painless lesions are typical of Kaposi's sarcoma in Caucasians. This is associated with HHV 8.

CMV and HHV 10 do not cause multiple violaceous painless lesions.

HPV 16 is an oncogenic virus which causes squamous cell carcinomas.

Pox virus causes molluscum contagiosum.

[Q: 3951] OnExamination 2012 - Infectious disease

A 27-year-old pop singer presented with a two month history of loose motions and weight loss. He underwent an HIV antibody test and was found to be positive.

The presence of which of the following diseases most likely indicates a diagnosis of AIDS?

- 1- Brucellosis
- 2- Glandular fever
- 3- Lyme disease
- 4- Oral candidiasis
- 5- Pulmonary tuberculosis

Answer & Comments

Answer: 5- Pulmonary tuberculosis

AIDS defining diseases are:

Cytomegalovirus disease (other than liver, spleen, or nodes)

Cytomegalovirus retinitis (with loss of vision)

Encephalopathy, HIV-related

Herpes simplex: chronic ulcer(s) (>1 month's duration); or bronchitis, pneumonia, or oesophagitis

Histoplasmosis, disseminated or extrapulmonary

Isosporiasis, chronic intestinal (>1 month's duration)

Kaposi's sarcoma

Lymphoma, Burkitt's (or equivalent term)

Lymphoma, primary, of brain

Mycobacterium avium complex or M. kansasii, disseminated or extrapulmonary

Mycobacterium tuberculosis, any site (pulmonary or extrapulmonary)

Mycobacterium, other species or unidentified species, disseminated or extrapulmonary

Pneumocystis carinii pneumonia

Pneumonia, recurrent

Progressive multifocal leukoencephalopathy

Salmonella septicaemia, recurrent

Toxoplasmosis of brain

Wasting syndrome due to HIV.

[Q: 3952] OnExamination 2012 - Infectious disease

An 82-year-old female is reviewed after the staff of the nursing home in which she resides expressed concern regarding a vaginal discharge.

She has been in the nursing home for the last year and has profound Alzheimer's dementia.

Culture of the discharge reveals Neisseria gonorrhoeae.

Which is the most appropriate course of action for this patient?

- 1- Contact the police
- 2- Contact tracing of sexual partners
- 3- Informal enquiry to the nursing home
- 4- Seek advice from the Medical Defence Union (MDU)
- 5- Treat the patient and discharge back to the nursing home

Answer & Comments

Answer: 4- Seek advice from the Medical Defence Union (MDU)

These ethical questions can be quite tough to answer with accuracy.

This question specifically relates to elder abuse, in this case potential elder sexual abuse. The scenario is one that is often played out in the press, in which a care worker sexually abuses elderly patients in his or her care.

However, you are given very little information here and what you would do is undoubtedly treat the patient and establish how she contracted gonorrhoea.

The question states that she has a profound dementia, suggesting that abuse has occurred rather than consensual sex. Nonetheless, you need to establish the facts. You have a personal duty of care to the patient and next of kin to do this before contacting the police.

It is likely that the police will need to be called but first it would be worth talking things through and obtaining advice from the MDU. The advice may entail investigating the set-up at the nursing home, talking with the next of kin, (and social services if a social worker has been involved) and finely detailing any injuries that may be present on examination.

Only then should the decision to contact the police be made.

[Q: 3953] OnExamination 2012 - Infectious disease

Seventeen of twenty-four passengers on a Nile cruise develop bloody diarrhoea on the third day.

Which of the following organisms is the likely cause?

- 1- Entamoeba histolytica
- 2- Giardia lamblia

- 3- Schistosoma mansoni
- 4- Shigella dysenteriae
- 5- Vibrio cholerae

Answer & Comments

Answer: 4- Shigella dysenteriae

Dysentery is characterised by the passing of frequent (sometimes very frequent) stools, that may contain blood, mucus or pus.

Shigella dysenteriae is responsible for bacillary dysentery, a disease most often associated with crowded, unsanitary conditions. Other species of Shigella may produce milder forms of diarrhoeal disease.

Dysentery is an oral infection transmitted via faecal contamination of water or food. During the one to four day incubation period, penetration of bacteria into the mucosal epithelial cells of the intestine causes an intense irritation of the intestinal wall, producing cramps and a watery, bloody diarrhoea.

[Q: 3954] OnExamination 2012 - Infectious disease

Which of the following statements regarding Japanese encephalitis is most true?

- 1- Is endemic in East Africa
- 2- It is a DNA virus
- 3- It is only recognised in travellers who have spent prolonged periods in endemic areas
- 4- Previous exposure to a flavivirus predisposes to increased risk of death on infection with Japanese encephalitis
- 5- Transplacental transmission occurs

Answer & Comments

Answer: 5- Transplacental transmission occurs

Japanese encephalitis is an RNA virus which is endemic in India, East Asia, Malaysia and the Phillipines.

Previous infection by a pathogen which is a member of the Flavivirus family seems to protect against serious disease or death when infection occurs with another member of the Flavivirus family. For instance previous exposure to dengue lowers the risk of death when infected by Japanese encephalitis.

Infection with Japanese encephalitis has been reported in travellers who have spent only short periods in endemic areas, and transplacental transmission can occur.

An immunisation is available for travellers.

[Q: 3955] OnExamination 2012 - Infectious disease

A 15-year-old girl presents with fever, malaise and sore throat.

Examination reveals a temperature of 38.3°C with cervical lymphadenopathy.

Her results show:

Haemoglobin 12.8 g/dL (11.5-16.5)

White cell count $9.8 \times 10^9/L$ (4-11 $\times 10^9$)

Neutrophils $3 \times 10^9/L$ (1.5-7 $\times 10^9$)

Lymphocytes $4.5 \times 10^9/L$ (1.5-4 $\times 10^9$)

Blood film reveals atypical mononuclear cells.

What is the most likely diagnosis?

- 1- Acute lymphoblastic leukaemia
- 2- Brucellosis
- 3- Epstein-Barr viral (EBV) infection
- 4- Hodgkin's disease
- 5- Sarcoidosis

Answer & Comments

Answer: 3- Epstein-Barr viral (EBV) infection

The diagnosis is EBV infection, infectious mononucleosis, which may be confirmed by the presence of immunoglobulin (Ig)M to EBV.

[Q: 3956] OnExamination 2012 - Infectious disease

A 70-year-old man presented to his GP with a two day history of increasing confusion. He also complained of a headache.

He was febrile on examination; nuchal rigidity was noted. A lumbar puncture was performed and CSF microscopy revealed:

WBC 800 cells/mL (< 5) 90% neutrophils. A few Gram positive diplococci were also noted.

What is the cause of his meningitis?

- 1- Cryptococcus neoformans
- 2- Haemophilus influenzae
- 3- Listeria monocytogenes
- 4- Neisseria meningitidis
- 5- Streptococcus pneumoniae

Answer & Comments

Answer: 5- Streptococcus pneumoniae

A question on Gram staining properties of organisms causing meningitis.

Pneumococcal meningitis is commoner in older patients.

Neisseria meningitidis is a Gram negative diplococcus whilst Haemophilus influenzae is a Gram negative bacillus.

Listeria monocytogenes is a cause of neonatal meningitis, and is a small Gram positive bacillus that is carried in the intestine and vagina and may be transmitted to the neonate during the birth process.

Cryptococcus neoformans is a fungus and yeast cells may be seen on microscopic examination of the cerebrospinal fluid (CSF).

[Q: 3957] OnExamination 2012 - Infectious disease

A 50-year-old man comes to clinic and asks for advice about his risk of infection.

Twenty years ago he had been involved in a road traffic accident and had sustained a splenic laceration, requiring an emergency splenectomy.

Which of the following options offers the best advice?

- 1- He does not need prophylactic antibiotics due to the amount of time that has elapsed since his surgery
- 2- He has no increased risk of acquiring malaria when travelling to an endemic region
- 3- He has no increased risk of infection since he has been well for 20 years following surgery
- 4- He should receive pneumococcal vaccine
- 5- There is no increased risk of infection in patients who undergo splenectomy due to trauma

Answer & Comments

Answer: 4- He should receive pneumococcal vaccine

Splenectomised patients are at increased risk of infection with encapsulated bacteria and infections that are filtered by the spleen (for example, malaria).

When elective splenectomy is planned, vaccines to pneumococcus and meningococcus should be given two weeks pre-surgery to allow an antibody response to evolve.

Patients who have emergency splenectomies should be vaccinated post-operatively, though the response may not be as efficient.

[Q: 3958] OnExamination 2012 - Infectious disease

An elderly woman who had her right first metatarsal amputated two weeks previously for diabetic gangrene, presented with right foot pain, rash and fever. There were features of inflammation around the amputated area.

Which one of the following investigations would you like to order to confirm the diagnosis?

- 1- Bone scan
- 2- CT scan
- 3- Indium-labelled leukocyte scanning
- 4- MRI scan
- 5- Right foot x ray

Answer & Comments

Answer: 4- MRI scan

Plain radiography of chronic osteomyelitis typically shows patchy osteopenia or frank bone destruction, loss of definition of the cortex, areas of sclerosis, or periosteal reaction with new bone formation. These changes take many weeks to develop fully.

For more rapid clarification of diagnosis however, specialised imaging is needed.

Computed tomography (CT) scanning may be able to identify cortical erosion that has been missed on plain films and can demonstrate sequestra within bone.

There is a lack of sensitivity early in the disease. White cell isotope scanning is widely used but there is a lack of consensus on the utility of various tests.

Conventional three-phase technetium bone scans are sensitive but non-specific. Specificity may be increased by the addition of indium-labelled leukocyte scanning.

Magnetic resonance imaging (MRI) is the standard and best method for diagnostic imaging of osteomyelitis. It can detect intra-

and extraosseous oedema, abscesses, dead bone, and sinus tracts. It can distinguish active from inactive infection.

[Q: 3959] OnExamination 2012 - Infectious disease

A 25-year-old Turkish woman arrived in the United Kingdom with a three month history of weight loss and intermittent fevers.

On examination, the patient was emaciated, febrile (39°C) and pale, and an enlarged liver (5 cm below the costal margin) and spleen (10 cm below the costal margin) were present.

Investigations revealed:

Haemoglobin 7.2 g/dL (11.5-16.5)

White cell count $2.4 \times 10^9/L$ (4-11 $\times 10^9$)

Platelet count $117 \times 10^9/L$ (150-400 $\times 10^9$)

Thick and thin films no parasites identified.

CXR normal.

What is the most likely diagnosis?

- 1- HIV infection
- 2- Infectious mononucleosis
- 3- Malaria
- 4- Miliary tuberculosis
- 5- Visceral leishmaniasis

Answer & Comments

Answer: 5- Visceral leishmaniasis

The clinical history given here is typical of visceral leishmaniasis.

Leishmaniasis is a vector-borne disease caused by obligate intra-macrophage protozoa, transmitted to humans by phlebotomine sandflies. It is endemic in large areas of the tropics, subtropics and Mediterranean basin. There are four main clinical syndromes: cutaneous, mucocutaneous, visceral (also known as kala-azar) and post kala-azar dermal leishmaniasis.

In cutaneous leishmaniasis patients generally present with ulcers or nodules. These usually heal spontaneously, but slowly, in immunocompetent individuals with resultant disfiguring scars.

Muco-cutaneous leishmaniasis is characterised by progressively destructive ulcerations of the mucosa extending from the nose and mouth to the pharynx and larynx, which are not self-healing. *Leishmania braziliensis* is responsible for the majority of these cases.

Post kala-azar dermal leishmaniasis is characterised by a macular, maculopapular or nodular rash and is a complication of visceral leishmaniasis frequently observed after treatment. It can also occur in immunosuppressed individuals, and is highly infectious.

Visceral leishmaniasis, as described here, is fatal if left untreated. It is caused by the *Leishmania donovani* complex (*L. donovani sensu stricto* in East Africa and India, and *L. infantum* in Europe, North Africa and Latin America). Following an incubation period of 2-6 months, patients present with persistent systemic infection (fever, malaise, loss of appetite and weight loss) and parasitic infection of the blood and reticulo-endothelial system (resulting in lymphadenopathy and hepatosplenomegaly). Anaemia is usually caused by persistent inflammation and hypersplenism, and can be exacerbated by bleeding.

Diagnosis can be difficult. Pancytopenia is often present, and is supportive of the diagnosis. There is also often marked polyclonal hypergammaglobulinaemia. Visualisation of the parasite (amastigote form) from lymph nodes, bone marrow or spleen is used as a confirmatory test. PCR can be used to detect the parasite in the blood. Anti-leishmanial antibodies can be detected, but they remain positive up to several years after cure and therefore cannot be used to detect

relapse. In addition there is a significant incidence of asymptomatic infection, and therefore seroprevalence in healthy populations.

Treatment of visceral leishmaniasis relies on specific therapies and aggressive management of concomitant infection, anaemia, hypovolaemia and malnutrition. First line antimonials are sodium stibogluconate and meglumine antimoniate. Adverse effects include cardiac arrhythmias and acute pancreatitis. Amphotericin B is increasingly being used. Vaccines are being developed, and novel drugs (including miltefosine and paromomycin) have been introduced. A elimination programme has been introduced to the Indian subcontinent.

Whilst opportunistic infections in HIV can present like this, there are no other indications in the question to suggest this is the diagnosis.

The history is too long for infectious mononucleosis.

Malaria is not common in Turkey, and we are told there are no parasites seen (although remember 3 negative films are needed to exclude the diagnosis).

Miliary TB is a possibility, but does not classically cause this level of hepatosplenomegaly.

[Q: 3960] OnExamination 2012 - Infectious disease

Which of the following is true of anthrax?

- 1- Eschars are usually painless.
- 2- Gastrointestinal anthrax is the most usual form of disease in humans.
- 3- It causes trivial disease in the host herbivore population.
- 4- It is caused by an aerobic, Gram negative rod.

- 5- Sputum culture has a high yield in inhalational anthrax.

Answer & Comments

Answer: 1- Eschars are usually painless.

Anthrax is caused by the Gram positive, aerobic, non-motile *Bacillus anthracis*.

It produces serious disease in the herbivore host and carnivores acquire the disease from either consuming the spores from the dead animal or by contact.

In humans, cutaneous disease is most common and a painless, black, indurated eschar frequently forms. Mortality from cutaneous disease is 20% if untreated whereas inhalational anthrax may have a mortality of 90% if untreated.

Inhalational anthrax is associated with a poor yield from sputum culture with the greatest yield from blood culture.

[Q: 3961] OnExamination 2012 - Infectious disease

A 25-year-old male has a history of travel to South East Asia on holiday for two weeks.

Five weeks ago he developed fever, pharyngitis, myalgia and a skin rash. The patient also has a generalised lymphadenopathy.

There two Paul-Bunnell tests which are negative one week apart.

What is the most likely diagnosis?

- 1- Acute HIV syndrome
- 2- CMV mononucleosis
- 3- Infectious mononucleosis
- 4- Streptococcal pharyngitis
- 5- Toxoplasmosis

Answer & Comments

Answer: 1- Acute HIV syndrome

With streptococcal pharyngitis the patient is more likely to have a sore throat, fever, chills, malaise and abdominal complaints. It has a short incubation period of one to four days. Both the Paul-Bunnell test and DNA polymerase chain reaction (PCR) for HIV will be negative.

Infectious mononucleosis has similar signs and symptoms to acute HIV syndrome but with a positive Paul-Bunnell test.

Cytomegalovirus (CMV) mononucleosis has a longer incubation period of 20-60 days. The illness takes two to six days. There are fever, chills, profound fatigue, malaise and myalgia.

With toxoplasmosis there are usually single or multiple enlarged cervical lymph nodes which are discrete, non-tender and vary in firmness.

The patient may also have

Fever

Headache

Malaise

Fatigue

Myalgia

Sore throat

Maculopapular rash

Meningoencephalitis

Confusion.

Cerebrospinal fluid (CSF) amplification DNA for toxoplasmosis gives the confirmatory diagnosis.

[Q: 3962] OnExamination 2012 - Infectious disease

A 35-year-old Nigerian female was assessed in an antenatal clinic. She was clinically well.

Antenatal screening for syphilis revealed the following results:

Treponemal EIA total Detected

Treponemal EIA IgM Not detected

Treponemal TPPA Detected 1:160

Treponemal RPR Not detected

What is the likely diagnosis?

- 1- Acute syphilis infection
- 2- Early latent syphilis infection
- 3- Late latent syphilis infection
- 4- Non-specific reactivity
- 5- Yaws

Answer & Comments

Answer: 3- Late latent syphilis infection

It is important that the serology is correctly interpreted and during pregnancy this lady is referred to a GU clinic for treatment with benzathine penicillin if not previously treated.

The detection of treponemal EIA total is confirmed by treponemal TPPA so this result is not a false positive. As treponemal IgM is not detected this is not consistent with acute infection.

In the absence of symptoms, late latent infection is more likely than early latent infection.

These results are unlikely to be cross reactivity secondary to yaws.

[Q: 3963] OnExamination 2012 - Infectious disease

Which one of the following drugs is associated with hypersensitivity reactions?

- 1- Atazanavir
- 2- Lamivudine
- 3- Nevirapine
- 4- Tenofovir
- 5- Zidovudine

Answer & Comments

Answer: 3- Nevirapine

Nevirapine can cause acute hepatitis and skin rash as a part of hypersensitive reaction especially when the CD4 count is over 250 cells/ml in women and over 400 cells/ml in men. Nevirapine should not be prescribed in those conditions.

Atazanavir causes hyperbilirubinaemia and rarely renal stones.

Lamivudine does not cause hypersensitivity reaction.

Tenofovir causes proximal tubular damage.

Zidovudine causes bone marrow suppression.

Reference:

Danino S, Yoganathan K, Jones P, Banner T. Urolithiasis in an HIV infected patient - a link with atazanavir? 2007; BHIVA spring meeting, Edinburgh.

[Q: 3964] OnExamination 2012 - Infectious disease

A 57-year-old woman develops a blistering rash around the midriff and is diagnosed with Herpes zoster. She is treated with aciclovir.

Which of the following is responsible for the activation of aciclovir?

- 1- Integrase
- 2- Polymerase
- 3- Protease
- 4- Reverse transcriptase
- 5- Thymidine kinase

Answer & Comments

Answer: 5- Thymidine kinase

This is a variation on the aciclovir theme.

Aciclovir acts through inhibition of viral deoxyribonucleic acid (DNA) polymerase but it

is a pro-drug and first requires phosphorylation by thymidine kinase.

[Q: 3965] OnExamination 2012 - Infectious disease

A 22-year-old woman is referred to hospital with a one week history of fever, headache and fatigue. She was a 'mail order' bride who had recently moved to the United Kingdom from Thailand to live with her new husband.

Based on her travel history which disease can be excluded from the following list of differentials?

- 1- Cerebral toxoplasmosis
- 2- HIV seroconversion illness
- 3- Japanese B encephalitis
- 4- Tuberculosis
- 5- Yellow fever

Answer & Comments

Answer: 5- Yellow fever

Yellow fever occurs only in tropical South America and in sub-Saharan Africa.

Japanese B encephalitis has a high prevalence in south east Asia.

All of the other diseases listed are widespread globally.

[Q: 3966] OnExamination 2012 - Infectious disease

A 22-year-old female student attended the casualty department complaining of fever and rigors for two days.

She had returned from a sabbatical in Africa six weeks previously.

She was febrile (39.9°C) and a mild petechial rash was also noted.

Laboratory investigations showed:

Hb 10.1 g/dL (11.5-16.5)

WBC $3.0 \times 10^9/L$ (4-11 $\times 10^9$)

Platelets $115 \times 10^9/L$ (150-400 $\times 10^9$)

Prothrombin time Normal

What is the most likely diagnosis?

- 1- Acute HIV infection (seroconversion illness)
- 2- Cytomegalovirus (CMV) infection
- 3- Dengue fever
- 4- Plasmodium falciparum malaria
- 5- Typhoid fever

Answer & Comments

Answer: 1- Acute HIV infection (seroconversion illness)

A difficult question that partly hinges on the incubation times of these illnesses.

The incubation time is too long for dengue, typhoid and falciparum malaria.

The presentation is not typical of CMV.

Acute human immunodeficiency virus (HIV) presents two weeks to three months after exposure to the virus; the illness typically consists of:

Fever

Arthritis

Rash

Lymphadenopathy.

The presentation given here is not characteristic of acute HIV, but is the most reasonable of the options listed.

[Q: 3967] OnExamination 2012 - Infectious disease

A 35-year-old man returned from a two week holiday complaining of pain in the loins and painful swollen knees.

On examination he was afebrile and had significant bilateral knee effusions. Mild penile erythema was also noted.

Laboratory investigations showed:

Hb 15.6 g/dl (13.0-18.0)

WBC $16.2 \times 10^9/L$ (4-11)

Neutrophils $14.1 \times 10^9/L$ (1.5-7)

ESR 65 mm/hr (0-15 mm/1st hr)

Rheumatoid factor 10 U/l

Urinalysis No cells, casts or bacteria seen

What is the most likely diagnosis?

- 1- Arthritis due to Neisseria gonorrhoeae infection
- 2- Lymphogranuloma venereum
- 3- Reactive arthritis
- 4- Reiter's syndrome
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 1- Arthritis due to Neisseria gonorrhoeae infection

The history is relatively acute with the arthritis and urethritis plus there is a neutrophilia.

The diagnostic possibilities include Reiter's or a gonococcal arthritis.

However, in this scenario, the acuteness of the illness on return from a holiday with no evidence of a preceding illness such as diarrhoea, and involvement of the larger joints, that is, knees, with effusions - suggests gonorrhoea.

Guidelines:

British Association for Sexual Health and HIV

[Q: 3968] OnExamination 2012 - Infectious disease

A 30-year-old man developed a febrile illness three days after returning from a holiday in Thailand. He was admitted complaining of severe myalgia.

On examination he was febrile (39 C) with a diffuse macular rash on the trunk. There was no lymphadenopathy.

Investigations revealed:

Haemoglobin 15.1 g/dL(13.0-18.0)

White cell count $7.5 \times 10^9/L$ (4-11)

Platelet count $105 \times 10^9/L$ (150-400)

Serum total bilirubin 18 $\mu\text{mol/L}$ (1-22)

Serum alanine aminotransferase 120 U/L(5-35)

What is the most likely diagnosis?

- 1- Acute HIV infection (seroconversion illness)
- 2- Dengue fever
- 3- Hepatitis E
- 4- Secondary syphilis
- 5- Typhoid

Answer & Comments

Answer: 2- Dengue fever

The symptoms are most consistent with dengue fever.

While acute retroviral syndrome (acute HIV) is associated with a widespread macular rash, it is also usually associated with pharyngitis and generalised lymphadenopathy.

Hepatitis E presents in a similar manner to hepatitis A, that is, as an acute febrile illness with jaundice.

The history is too acute for secondary syphilis, which is not typically associated with myalgia.

Typhoid fever is usually a diarrhoeal illness associated with subtle 'rose spots' on the abdomen.

Dengue fever is caused by an arthropod-borne Flavivirus. The disease has an incubation period of approximately seven days, followed by headaches and retro-orbital pain. Symptoms evolve rapidly and severe musculoskeletal pain is a prominent feature, with a maculopapular rash.

[Q: 3969] OnExamination 2012 - Infectious disease

Which of the following investigations is used to monitor the treatment of infective endocarditis?

- 1- Blood culture
- 2- C reactive protein
- 3- Echocardiography
- 4- Erythrocyte sedimentation rate
- 5- Serum bactericidal titres of antibiotics

Answer & Comments

Answer: 2- C reactive protein

Serum bactericidal titres against the infecting organism are no longer recommended.

There was always great variation in the monitoring methods used for these tests and in the interpretation of their results. At best they could only predict bacteriological not clinical cure, and bacteriological failure is very rare.

The most useful laboratory test for monitoring the response to treatment (which is usually obvious clinically) is serial C reactive protein estimation.

This is of much more use than the erythrocyte sedimentation rate, which is much slower to fall.

[Q: 3970] OnExamination 2012 - Infectious disease

Which of the following infections is least likely to cause myocarditis?

- 1- Chagas disease
- 2- Coxsackie virus
- 3- Diphtheria
- 4- Syphilis
- 5- Toxoplasmosis

Answer & Comments

Answer: 4- Syphilis

Quaternary syphilis involves the cardiovascular system, commonly in the form of ascending aortic aneurysm and aortic regurgitation.

Diphtheria, coxsackie virus, Chagas disease and toxoplasmosis are all associated with myocarditis.

[Q: 3971] OnExamination 2012 - Infectious disease

A 63-year-old female presents with a one day history of confusion with headaches.

On examination she is confused, with a Glasgow coma scale of 13 and a temperature of 39.5°C.

She has nuchal rigidity and photophobia.

CSF examination reveals a glucose of 0.5 mmol/l (3.3-4.4), a white cell count of 2500 per mm and Gram positive cocci in pairs.

Which of the following is correct?

- 1- A characteristic rash would be expected
- 2- Nerve deafness would be a common complication in this case
- 3- Rifampicin should be given to close contacts
- 4- The most likely infective organism is Staphylococcus aureus
- 5- The organism is likely to be penicillin resistant

Answer & Comments

Answer: 2- Nerve deafness would be a common complication in this case

This patient has pneumococcal meningitis, caused by the Gram positive coccus Strep. pneumoniae.

This is the second commonest cause of bacterial meningitis (commonest in the elderly) and is associated with the highest

mortality (20%) and highest morbidity, such as deafness which may occur in 50%.

Contacts do not require treatment and there is no rash associated with pneumococcal meningitis.

Meningococcus is Gram negative.

[Q: 3972] OnExamination 2012 - Infectious disease

A 69-year-old male presented with fever and difficulty in breathing.

He is alert and well co-ordinated with respect to time and place but has trouble placing words or pictures into categories. He used to be bilingual but now has lost the ability to speak French and he can speak only English. He also has trouble following some verbal commands.

The coronal FLAIR magnetic resonance image looks as follows:

What is the most likely diagnosis?

- 1- Cryptococcal meningitis
- 2- Haemophilus meningitis
- 3- Herpes simplex encephalitis
- 4- Neurosyphilis
- 5- Progressive multifocal leukoencephalopathy

Answer & Comments

Answer: 3- Herpes simplex encephalitis

Herpes simplex encephalitis affects the temporal lobe in most cases.

If the temporal lobe is affected the following signs will be seen:

Disturbance of auditory sensation and perception

Disturbance of selective attention to auditory and visual input

Disorders of visual perception

Impaired organisation and categorisation of verbal material

Disturbance of language comprehension

Impaired long term memory

Altered personality and affective behaviour and

Altered sexual behaviour.

The MRI just confirms the diagnosis.

Cryptococcal meningitis is the wrong answer because it is a lot more common in people with a lowered immunity. Its common symptoms are often:

Headache

Altered mental status including personality changes

Confusion

Lethargy

Obtundation and

Coma.

Haemophilus meningitis is often preceded by an upper respiratory illness. Initial manifestations include:

Lethargy

Fever

Headache

Photophobia

Meningitis

Irritability

Anorexia

Nausea or

Vomiting.

Neurosyphilis often manifests with:

Psychosis

Delirium and

Dementia.

There could be history of a painless ulcerative chancre.

Progressive multifocal leukoencephalopathy is usually found in people with a lowered immunity such as diabetes, HIV/AIDS and on cancer chemotherapy. There are usually:

Headaches

Loss of co-ordination

Loss of language ability

Memory loss

Vision problems and

Weakness of the legs and arms.

It is diagnosed by finding the JC viruses by DNA polymerase chain reaction (PCR) from the cerebrospinal fluid (CSF).

[Q: 3973] OnExamination 2012 - Infectious disease

A 24-year-old patient presents with acute lymphoblastic leukaemia for which she is taking chemotherapy.

One week after having her glucocorticoids tapered the patient now reports having a cough with progressive difficulty in breathing, a fever and night sweats.

On examination the patient has severe dyspnoea, central cyanosis and is febrile to touch. The patient has oral thrush. Her temperature 38.5°C, BP 118/76 mmHg and HR-140 beats/minute.

The oxygen saturation is 84% at rest and 76% on exertion. The respiratory rate is 40 beats/minute, there are some basal crepitations and the rest of the examination findings are not significant.

On doing a bronchial alveolar lavage and stained with methenamine silver the patient's chest radiograph looks as follows.

What is the most likely diagnosis?

- 1- Legionellosis
- 2- Lymphocytic interstitial pneumonia
- 3- Pneumocystis jiroveci pneumonia
- 4- Pulmonary embolism
- 5- Tuberculosis

Answer & Comments

Answer: 3- Pneumocystis jiroveci pneumonia

The clinical manifestations above are of PCP.

The disease usually develops after one to two weeks of tapering the dose of the steroids. It is usually progressive, with worsening dyspnoea, a dry cough, weight loss and night sweats.

The signs on examination usually depend on the severity of the disease. The chest radiography often shows various manifestations, and is not diagnostic but usually shows diffuse infiltrates, sparing mainly the upper and lower zones. PCP can be stained with methenamine silver where it attaches to the walls of the Pneumocystis jiroveci pneumonia.

Legionellosis is the wrong answer because these patients often have temperatures greater than 40°C, chills, cough and pleuritic chest pain. There is also a likelihood of neurological symptoms such as headache, lethargy, encephalopathy and mental state changes.

Lymphocytic interstitial pneumonia is the wrong option despite it being similar to Pneumocystis carinii pneumonia by causing a fever, cough and dyspnoea. These patients could also have a generalised lymphadenopathy, hepatomegaly and parotid enlargement which are not found in PCP.

PCP is similar to an acute pulmonary infarction which often presents with pleuritic chest pain, breathlessness, haemoptysis and a fever.

Patients with tuberculosis often have a productive cough for more than two weeks with weight loss, night sweats and evening fevers. There is more likely to be some chest pain and difficulty in breathing.

[Q: 3974] OnExamination 2012 - Infectious disease

A 19-year-old gap year student presents to the GP feeling unwell with fevers, lethargy, right upper quadrant pain, a dry cough and shortness of breath over the past few days. She has returned from an operation Raleigh assignment in Uganda a few weeks ago.

Her only past medical history of note is that she reports an itchy area of skin on her upper thigh shortly after swimming in a local lake. Examination is unremarkable apart from some right upper quadrant tenderness.

Investigations show

Haemoglobin 11.4 g/dl(11.5-16.5)

White cell count $11.2 \times 10^9/L$

(Raised eosinophils) (4-11)

Platelets $180 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely diagnosis?

- 1- Churg-Strauss syndrome
- 2- Extrinsic allergic asthma
- 3- Hydatid disease
- 4- Schistosomiasis
- 5- Weil's disease

Answer & Comments

Answer: 4- Schistosomiasis

The initial area of itching may be related to swimmers' itch, which is related to the entry of the parasite through the skin after

swimming in an area where the parasite is present in water.

The raised eosinophil count supports the diagnosis, and the dry cough raises the possibility of parasitic migration to the lungs. Diagnosis is based upon the presence of parasites in the stool, or in the urine in the case of *S. haematobium*.

Praziquantel is the treatment of choice, given as a single dose with follow up in four to six weeks.

[Q: 3975] OnExamination 2012 - Infectious disease

A 62-year-old lady is due to attend her dentist for a hygiene appointment for scaling.

She has a history of mitral valve prolapse with regurgitation and is allergic to penicillin.

Which of the following antibiotics would be the most appropriate choice for prophylaxis in this lady?

- 1- No antibiotic prophylaxis
- 2- Oral clindamycin
- 3- Oral doxycycline
- 4- Oral erythromycin
- 5- Oral ofloxacin

Answer & Comments

Answer: 1- No antibiotic prophylaxis

NICE guidance Of 2008 suggests that prophylaxis is not required during dental procedures.

[Q: 3976] OnExamination 2012 - Infectious disease

A patient presents with a 36 hour history of Varicella zoster in the T4 dermatome. She complains of severe pain in the skin supplied by T4.

What is the most appropriate management?

- 1- Aciclovir
- 2- Carbamazepine
- 3- Famciclovir
- 4- Nothing
- 5- Prednisolone

Answer & Comments

Answer: 1- Aciclovir

Aciclovir and famciclovir may be used to treat herpes zoster. They both reduce time to healing and resolution of associated pain.

Aciclovir is now a generic medication and therefore will be cheaper than famciclovir and is the most cost effective of the treatments listed.

Early use of steroids in herpes zoster may also reduce the amount of analgesia required and the length of illness.

BMJ wrote a clinical review of the treatment of herpes zoster in 2003. The main take home message was that appropriate treatment of herpes zoster can control acute symptoms and reduce the risk of longer term complications. You need a log in to obtain full access to the article but a summary is provided free of charge.

In March 2010, NICE updated their guidance on the treatment of neuropathic pain. First line treatment of post herpetic neuralgia would now include amitriptyline or pregabalin.

CKS have also issued guidance on the treatment of herpes zoster. This guidance is generally in keeping with that issued by NICE. They add that, although carbamazepine has evidence to support its use in the treatment of post herpetic neuralgia, the potential for serious adverse side effects and the lack of a license has prevented them from recommending it as a primary care treatment.

[Q: 3977] OnExamination 2012 - Infectious disease

A 57-year-old woman develops a blistering rash around the midriff and is diagnosed with herpes zoster.

She is treated with aciclovir.

Through inhibition of which of the following does aciclovir function?

- 1- Integrase
- 2- Polymerase
- 3- Protease
- 4- Reverse transcriptase
- 5- Thymidine kinase

Answer & Comments

Answer: 2- Polymerase

Aciclovir is a synthetic purine nucleotide analogue and as such is a specific inhibitor of herpesvirus DNA polymerase.

[Q: 3978] OnExamination 2012 - Infectious disease

A 38-year-old male with a diagnosis of HIV presents with lethargy, confusion, personality change and a seizure.

CT shows multiple ring enhancing mass lesions in both cerebral hemispheres.

What treatment is indicated?

- 1- Broad spectrum antibiotics
- 2- Corticosteroids
- 3- Ketoconazole
- 4- Pyrimethamine and sulfonamide
- 5- Rifampicin and pyrazinamide

Answer & Comments

Answer: 4- Pyrimethamine and sulfonamide

Cerebral Toxoplasma infection gives rise to multiple ring enhancing lesions on CT and MRI scanning.

Multiple cerebral abscesses are commonly present, which may result in multifocal symptoms, including

Visual field deficits

Focal seizures

Aphasia

Hemiparesis or hemisensory deficits

Cranial nerve palsies

Cerebellar dysfunction.

Non-focal symptoms such as a confusional state or personality disorder may manifest initially, but focal symptoms eventually appear as the disease progresses.

[Q: 3979] OnExamination 2012 - Infectious disease

A 15-year-old boy is referred by his GP with a two week history of general malaise, fatigue and pharyngitis.

On examination multiple small lymph nodes were palpable in the neck, axillae and groins.

Investigations revealed:

Haemoglobin 12.5g/dl(13.0-18.0)

WBC $16.0 \times 10^9/L$ (4-11)

Platelets $160 \times 10^9/L$ (150-400)

Blood film Lymphocytosis noted

What is the most likely diagnosis?

- 1- Acute lymphoblastic leukaemia
- 2- Cytomegalovirus infection
- 3- Epstein-Barr virus infection
- 4- Hodgkin's disease
- 5- Toxoplasmosis

Answer & Comments

Answer: 3- Epstein-Barr virus infection

Acute Epstein-Barr virus (EBV) typically presents with a history of one to two weeks of

fatigue and malaise, fever, pharyngitis, and symmetrical, bilateral lymphadenopathy. Heterophil antibody tests are usually positive. Mild transient thrombocytopenia is not uncommon in EBV infectious mononucleosis.

Cytomegalovirus (CMV) mononucleosis has a lower incidence of pharyngitis and cervical adenopathy.

Primary toxoplasmosis is acquired via ingestion of undercooked meat containing toxoplasma cysts, or ingestion of fresh food contaminated by toxoplasma excreted in cats' faeces. The infection is asymptomatic in 80-90% of immunocompetent patients.

Highly characteristic of toxoplasmosis is asymmetrical lymphadenopathy limited to an isolated lymph node group. Patients with toxoplasmosis have little or no fever, fatigue, or pharyngitis.

CMV infectious mononucleosis may be indistinguishable in clinical presentation from EBV but is usually not accompanied by posterior cervical adenopathy; non-exudative pharyngitis is minimal or absent.

The diagnosis of acute lymphoblastic leukaemia (ALL) and Hodgkin's disease (HD) is made by a combination of blood film examination, bone marrow aspiration and biopsy and lymph node biopsy.

[Q: 3980] OnExamination 2012 - Infectious disease

A 35-year-old woman presents with fever, rigors, malaise and weight loss.

She had undergone prosthetic valve replacement one month before. C3 level was reduced and echocardiography showed small vegetations.

Which micro-organism is most likely to be responsible for this?

- 1- Candida
- 2- Coxiella burnetii

- 3- Staphylococcus aureus
- 4- Staphylococcus epidermidis
- 5- Streptococcus viridans

Answer & Comments

Answer: 4- Staphylococcus epidermidis

Prosthetic valve endocarditis arising within two months of valve surgery is generally the result of intraoperative contamination of the prosthesis or a bacteraemia postoperative complication.

The nosocomial nature of these infections is reflected in their primary microbial causes:

Coagulase-negative staphylococci (Staphylococcus epidermidis)

S. aureus

Facultative Gram negative bacilli

Diphtheroids

Fungi.

Wang A, Athan E, Pappas PA, Fowler VG Jr, Olaison L, Paré C, et al. Contemporary clinical profile and outcome of prosthetic valve endocarditis. JAMA. Mar 28 2007;297(12):1354-61.

Whilst a recent study (Wang A, Athan E, Pappas PA, Fowler VG Jr, Olaison L, Paré C, et al. Contemporary clinical profile and outcome of prosthetic valve endocarditis. JAMA. Mar 28 2007;297(12):1354-61) did show that staphylococcal aureus was the most common cause of prosthetic valve infective endocarditis it is thought that this may have been due to recruitment or referral bias. The trend has not been replicated in all subsequent studies. Therefore, for the exam it is safer currently to state that Staphylococcus epidermidis is the commonest colonising organism within 6 months of implantation of a prosthetic valve.

The oral cavity, skin, and upper respiratory tract are the respective primary portals for the viridans Streptococci, Staphylococci, and

HACEK organisms (Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, and Kingella), causing community-acquired native valve endocarditis.

Streptococcus bovis originates from the gastrointestinal tract, where it is associated with polyps and colonic tumours, and Enterococci enter the bloodstream from the genitourinary tract.

[Q: 3981] OnExamination 2012 - Infectious disease

A 50-year-old man presented to hospital feeling generally unwell for three days.

He had returned from a business trip to Thailand six weeks previously and had taken mefloquine as prophylaxis against malaria.

On examination he was afebrile, temperature 36.5°C, pulse was 100/minute and regular, his BP was 85/60 mm Hg.

Investigations showed:

Hb 14.2 g/dL (13.0-18.0)

WBC 19.0 x 10⁹/L (4-11 x10⁹)

Neutrophils 18.0 x 10⁹/L (1.5-7.0 x10⁹)

AST 72 U/L (1-31)

Alkaline phosphatase 255 U/L (45-105)

What is the most likely diagnosis?

- 1- Acute HIV infection (seroconversion illness)
- 2- Dengue fever
- 3- Gram negative bacteraemia
- 4- Hepatitis B
- 5- Mefloquine-induced hepatitis

Answer & Comments

Answer: 3- Gram negative bacteraemia

A difficult question.

The neutrophilia essentially excludes most viral causes.

The presentation is not typical of acute human immunodeficiency virus (HIV) (fever, pharyngitis, rash and lymphadenopathy).

Mefloquine can cause abnormal liver function tests, but is not common.

Even though the patient is afebrile, the likeliest diagnosis is therefore Gram negative bacteraemia.

[Q: 3982] OnExamination 2012 - Infectious disease

Which of the following is correct regarding toxoplasmosis?

- 1- Can present with fits in patients with AIDS
- 2- Infection in the first trimester of pregnancy is seldom harmful to fetus
- 3- Infection is usually by respiration
- 4- Prophylactic immunoglobulins should be given to pregnant women if their IgM anti-toxoplasma antibodies detected
- 5- Raw eggs are an important source of infection

Answer & Comments

Answer: 1- Can present with fits in patients with AIDS

Transmission of Toxoplasma gondii occurs after ingestion of cysts from contact with cat faeces or raw/undercooked meat. The definitive host is the cat.

Oocysts excreted with cat faeces can remain in soil for months.

Risk of fetopathy is reduced by more than 50% if spiramycin, which can prevent maternal-fetal transmission, is given to mothers.

[Q: 3983] OnExamination 2012 - Infectious disease

A 43-year-old Pakistani female presents with a two month history of weight loss, fever and

night sweats.

Chest x ray reveals a large right sided pleural effusion.

What investigation is most likely to confirm a diagnosis of suspected TB?

- 1- CT scan of thorax
- 2- Interferon gamma releasing assay (IGRA)
- 3- Pleural aspirate
- 4- Pleural biopsy
- 5- Sputum analysis

Answer & Comments

Answer: 4- Pleural biopsy

For suspected pleural TB, pleural biopsy sent in normal saline for AFB smear, mycobacterial culture and histology is the most sensitive method for laboratory confirmation.

In cases of suspected TB, every effort should be made to confirm a suspected diagnosis by culture.

Susceptibility testing is important as detection of resistance alters the combination of drugs and duration of treatment.

[Q: 3984] OnExamination 2012 - Infectious disease

A 36-year-old Caucasian woman was successfully treated for *Pneumocystis jirovecii* pneumonia (PCP).

She was re-admitted with acute breathlessness with left-sided chest pain ten days after her discharge from the hospital. Examination revealed that she was hypoxic and found to have diminished breath sounds on the left side of chest.

What is the most likely cause of her recent admission?

- 1- Acute myocardial infarction
- 2- Acute pericarditis
- 3- Acute pulmonary embolism

4- Left lobar pneumonia

5- Pneumothorax

Answer & Comments

Answer: 5- Pneumothorax

Pneumothorax is a well-known complication of PCP. An acute history of chest pain with breathlessness and diminished breath sounds is typical of pneumothorax.

Diminished breath sounds are not a feature of acute myocardial infarction or acute pericarditis.

Acute pulmonary embolism should be considered due to her recent admission but diminished breath sounds are not a feature.

There are no signs of consolidation to consider lobar pneumonia.

[Q: 3985] OnExamination 2012 - Infectious disease

A 50-year-old female presents with dyspnoea, a new murmur and fever and is diagnosed with infective endocarditis.

Which of the following is associated with the best prognosis?

- 1- Aortic valve infection
- 2- Culture negative endocarditis
- 3- Low complement levels
- 4- *Staphylococcus aureus* infection
- 5- *Streptococcus viridans* infection

Answer & Comments

Answer: 5- *Streptococcus viridans* infection

Features suggestive of a worse prognosis are:

Acute endocarditis (*Staphylococcus aureus*)

Heart failure

Intravenous drug abuse (often left and right sided disease)

Prosthetic valve infection

Infection of the aortic rather than mitral valve

Associated rhythm disturbance.

Subacute bacterial endocarditis
(Streptococcus viridans) has a better prognosis.

[Q: 3986] OnExamination 2012 - Infectious disease

A 41-year-old male has been diagnosed with infective endocarditis.

Which of the following is associated with the best prognosis?

- 1- Aortic valve infection
- 2- Intravenous drug abuse
- 3- Prosthetic valve infection
- 4- Staphylococcus aureus infection
- 5- Streptococcus viridans infection

Answer & Comments

Answer: 5- Streptococcus viridans infection

Features suggestive of a worse prognosis are

Acute endocarditis (Staphylococcus aureus)

Heart failure

IV drug abuse (often left and right sided disease)

Prosthetic valve infection

Infection of the aortic rather than mitral valve

Associated rhythm disturbance.

Subacute bacterial endocarditis
(Streptococcus viridans) has a better prognosis.

[Q: 3987] OnExamination 2012 - Infectious disease

A 65-year-old woman is diagnosed as having subacute bacterial endocarditis and

appropriate antibiotic therapy started.

Which of the following investigations is the most useful in order to monitor her response to antibiotics?

- 1- Serial blood cultures
- 2- Serial full blood count, monitoring the white cell count
- 3- Serial transthoracic echocardiography
- 4- Serum bactericidal activity
- 5- Serum C reactive protein (CRP) concentration

Answer & Comments

Answer: 5- Serum C reactive protein (CRP) concentration

C reactive protein (CRP) is a member of the pentraxin protein family, and levels are greatly elevated during acute inflammation.

CRP augments the immune response to certain antigens, activates complement, and increases the monocytic production of certain tissue factors.

CRP binds to bacterial surfaces, acting as an opsonin.

CRP concentrations are elevated in almost all inflammatory, infectious, and malignant diseases.

Serial measurements of CRP concentrations provide a simple, effective, non-invasive means of measuring response to antibiotic therapy.

[Q: 3988] OnExamination 2012 - Infectious disease

A 40-year-old farmer presented to the Emergency department with a 24 hour history of fever and increasing confusion.

On examination he was febrile 39.5°C. A generalised erythematous rash covering most of his body was observed. He also had a paronychia infection of his right index finger

with lymphangitis extending caudally and with axillary lymphadenopathy.

His heart rate was measured at 120 beats per minute with a blood pressure of 80/60 mmHg.

What is the most likely diagnosis?

- 1- Hantavirus infection
- 2- Leptospirosis
- 3- Orf
- 4- Staphylococcal toxic shock syndrome
- 5- Stevens-Johnson syndrome

Answer & Comments

Answer: 4- Staphylococcal toxic shock syndrome

The history is typical of staphylococcal toxic shock syndrome (TSS):

Shock

Fever

Confusion

Rash.

The primary source of infection in this case is the paronychia of his right index finger.

Hantavirus infections (viral zoonoses transmitted via rodents) typically have two distinct presentations, either

As a haemorrhagic fever with renal failure, or

As an acute pulmonary syndrome.

The former manifestation is commonest in the Far East and eastern Europe, while the latter is the predominant form in the southwestern United States and South America.

Leptospirosis does not typically cause a rash and is often associated with jaundice; leptospirosis would not explain the lesion on his finger.

Orf, a zoonotic infection caused by a pox virus, presents with painless ulcerated lesions on the

hands of farmers, but does not fully explain this clinical picture.

Stevens-Johnson syndrome typically starts with an erythema multiforme-type rash that spreads widely and involves the buccal mucosa and conjunctivae, often caused by antibiotic therapy; but does not fit the clinical picture presented here.

[Q: 3989] OnExamination 2012 - Infectious disease

A 15-year-old girl presents to casualty with mild gastrointestinal upset. She had recently returned from holiday where she had been swimming in the hotel pool.

What is the most likely causative organism?

- 1- Campylobacter jejuni
- 2- Cryptosporidium parvum
- 3- Salmonella enteridis
- 4- Shigella flexneri
- 5- Staphylococcus aureus

Answer & Comments

Answer: 2- Cryptosporidium parvum

Human cryptosporidiosis causes self-limited diarrhoeal illness in healthy individuals, mostly children; and severe prolonged diarrhoea in patients with AIDS.

Transmission is via human-to-human fecal-oral contamination.

Animals are the major reservoir and outbreaks have been associated with water supplies and public swimming pools.

[Q: 3990] OnExamination 2012 - Infectious disease

Which of the following statements concerning zoonotic diseases is true?

- 1- Brucellosis is characterised by neutrophil leucocytosis

- 2- Brucellosis is a recognised cause of spondylitis
- 3- Serological evidence of toxoplasmosis is rare in adults
- 4- Toxoplasmosis causes vasculitic anterior uveitis
- 5- Toxoplasmosis causes visceral larva migrans

Answer & Comments

Answer: 2- Brucellosis is a recognised cause of spondylitis

Brucellosis is a zoonosis, spreading from infected animals particularly cattle. There are four species: melitensis, abortus, suis, and canis.

Pasteurisation of milk has dramatically decreased the incidence in the UK.

Brucella are Gram negative bacilli which are fastidious. There is usually a history of exposure, and the symptoms are rather non-specific with fever, malaise, arthralgia and depression. Thirty five per cent have hepatosplenomegaly.

Leukopaenia is common, and 75% have a positive blood culture (90% of bone marrow cultures will be positive).

Toxoplasma is most frequent in farming communities where contact occurs with cats, and patients eat raw meat. Clinical manifestations include:

Focal choroidoretinitis

Granulomatous uveitis

Optic atrophy

Retinal detachment

Cataract

Posterior uveitis

Glaucoma.

[Q: 3991] OnExamination 2012 - Infectious disease

Which of the following is the drug of choice for the treatment of Chlamydia trachomatis infection during pregnancy?

- 1- Amoxicillin
- 2- Cephalosporin
- 3- Clindamycin
- 4- Metronidazole
- 5- Tetracycline

Answer & Comments

Answer: 1- Amoxicillin

Chlamydia infection in the non-pregnant state is usually treated with a tetracycline, or with erythromycin. More recently, however, amoxicillin has been found to be as effective as the latter.

During pregnancy, tetracycline therapy is contraindicated because of its incorporation into fetal bones and teeth.

Thus, of the options listed, amoxicillin is the drug of choice.

[Q: 3992] OnExamination 2012 - Infectious disease

A 70-year-old woman developed herpes zoster ophthalmicus.

Which one of the following is most likely to be a complication of this condition?

- 1- Hyphaema
- 2- Keratitis
- 3- Keratoconus
- 4- Posterior subcapsular cataract
- 5- Scleromalacia

Answer & Comments

Answer: 2- Keratitis

Keratitis due to varicella zoster virus (VZV) may subsequently lead to iridocyclitis and secondary glaucoma.

[Q: 3993] OnExamination 2012 - Infectious disease

Of which of the following is chronic liver disease not a complication?

- 1- Alpha1 antitrypsin deficiency
- 2- Cystic fibrosis
- 3- Haemochromatosis
- 4- Haemosiderosis
- 5- Hepatitis C

Answer & Comments

Answer: 4- Haemosiderosis

Fifty percent of hepatitis C infections lead to chronic liver disease (treat with interferon-a).

Liver disease from chronic cholestasis occurs in cystic fibrosis.

Alpha1 antitrypsin deficiency causes both cirrhosis and emphysema.

Haemochromatosis is autosomal recessive and is characterised by excessive iron deposition in various organs causing organ failure (diabetes, heart failure, chronic liver disease, hypogonadism, skin pigmentation and arthritis).

Haemosiderosis usually arises due to parenteral iron overload, for example, in patients with aplastic anaemia after multiple transfusions. It is not commonly associated with cirrhosis.

If cirrhosis does develop as a result of massive iron overload the condition is known as secondary haemochromatosis.

[Q: 3994] OnExamination 2012 - Infectious disease

A sexually active female presents to a GU

clinic with multiple painful genital ulcers.

What is the likeliest cause?

- 1- Chlamydia trachomatis
- 2- Herpes simplex
- 3- Haemophilus ducreyi
- 4- Primary HIV infection
- 5- Treponema pallidum

Answer & Comments

Answer: 2- Herpes simplex

Herpes simplex is a sexually transmitted disease and the commonest cause of multiple painful genital lesions.

C. trachomatis and T. pallidum do not normally cause painful genital ulceration.

H. ducreyi does cause painful genital ulcers, however there is usually only a single ulcer present and it is much less common than Herpes simplex in the UK. It remains highly prevalent in areas of Africa.

Compared to herpes simplex, primary human immunodeficiency virus (HIV) infection is an unusual cause of genital ulceration.

[Q: 3995] OnExamination 2012 - Infectious disease

A 27-year-old man comes to the Emergency department with his partner at 5 am. He has developed torrential diarrhoea a few hours after eating a Chinese takeaway with fried rice. Apparently he bought the meal at the beginning of the evening when he thought it would be most fresh.

On examination he is dehydrated with a BP of 110/70 mmHg, a pulse of 90 and a significant postural drop.

Investigations show:

Haemoglobin 15.0 g/dl (13.5-17.7)

White cell count $6.6 \times 10^9/L$ (4-11)

Platelets $292 \times 10^9/L$ (150-400)

Serum Sodium 142 mmol/l (135-146)

Serum Potassium 3.7 mmol/l (3.5-5)

Creatinine 122 μ mol/l (79-118)

Which of the following is the most likely cause of his gastroenteritis?

- 1- Bacillus cereus
- 2- Norovirus
- 3- Rotavirus
- 4- Staphylococcus aureus
- 5- Staphylococcus typhi

Answer & Comments

Answer: 1- Bacillus cereus

Bacillus cereus food poisoning occurs around six to eight hours after ingestion of reheated rice. Two distinct forms occur, one related to a toxin which leads to profuse vomiting, the other which leads to torrential diarrhoea.

It is likely the takeaway restaurant reheated rice that was left over from the previous evening.

The condition is self-limiting and usually resolves within 24 hours. No specific intervention is required, and this patient should just be given oral rehydration salts.

[Q: 3996] OnExamination 2012 - Infectious disease

A 67-year-old man is referred with symptoms of fatigue and a low grade fever. He has lost a few pounds in weight over the past few weeks and suffered from persistent night sweats.

Past history of note includes chronic gum disease and a number of broken teeth. He is also allergic to penicillin.

On examination he has a temperature of 37.8°C, and his BP is 105/70 mmHg with a pulse of 95. There are splinter haemorrhages on examination of the fingers on both hands.

He has a systolic murmur loudest in the mitral area.

Investigations show

Haemoglobin 10.8 g/dl (13.5-18)

White cell count $11.1 \times 10^9/L$ (4-10)

Platelets $201 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 4.5 mmol/l (3.5-5)

Creatinine 135 μ mol/l (60-120)

C reactive protein 125 mg/l (<10)

Which of the following is the most appropriate empirical antibiotic regime?

- 1- Benzylpenicillin and gentamicin
- 2- Ceftazidime and metronidazole
- 3- Flucloxacillin and gentamicin
- 4- Linezolid and gentamicin
- 5- Vancomycin and gentamicin

Answer & Comments

Answer: 5- Vancomycin and gentamicin

Viridans or Bovis streptococci would figure very high on the index of suspicion, as causes of endocarditis here. As such, in the presence of penicillin allergy, guidelines from the Royal College recommend vancomycin and gentamicin combination therapy as the best alternative to benzylpenicillin and gentamicin.

Flucloxacillin and gentamicin is the regime of choice for methicillin sensitive Staphylococcus aureus, with linezolid an appropriate alternative in MRSA.

[Q: 3997] OnExamination 2012 - Infectious disease

Which one of the following antiretrovirals is likely to cause increased pigmentation of the skin in a black African patient?

- 1- Didanosine
- 2- Efavirenz

- 3- Emtricitabine
- 4- Nevirapine
- 5- Stavudine

Answer & Comments

Answer: 3- Emtricitabine

Emtricitabine causes hyperpigmentation of skin including palmar creases in 8% of black patients.

Didanosine and stavudine cause mitochondrial toxicity, hence peripheral neuropathy, pancreatitis and hyperlactataemia.

Efavirenz causes CNS toxicity.

Nevirapine causes acute hepatitis and skin rash.

[Q: 3998] OnExamination 2012 - Infectious disease

A 45-year-old HIV-seropositive man attended the outpatient clinic for the results of a fasting serum lipid test.

He had been diagnosed with HIV disease two years previously and was started on highly active antiretroviral therapy. One year after commencing antiretrovirals, his CD4 count had risen from 10 cells/ mm³ to 120 cells/ mm³ with an undetectable viral load.

His current medications consisted of zidovudine, lamivudine, lopinavir, aciclovir, fluconazole and co-trimoxazole.

Fasting lipid profile revealed:

Serum cholesterol 4.1 mmol/l (<5.2)

Serum triglyceride 18.2 mmol/l (0.45-1.69)

Which of the following medications is most likely to be responsible for these results?

- 1- Co-trimoxazole
- 2- Fluconazole
- 3- Lamivudine
- 4- Lopinavir

- 5- Zidovudine

Answer & Comments

Answer: 4- Lopinavir

Lipodystrophy, lipoatrophy and alterations in serum lipid values have been observed in patients with human immunodeficiency virus (HIV) disease taking highly active antiretroviral therapy.

Elevated serum lipid levels have been associated with premature coronary artery disease.

Hypertriglyceridaemia is also thought to contribute to central fat deposition, and insulin resistance that is also seen in these patients.

Abnormalities of serum lipid levels are likely to be multifactorial in patients with HIV disease, but appear much commoner in patients taking protease inhibitors.

Isolated hypertriglyceridaemia can occur in HIV disease in the absence of protease inhibitors, but extremely high serum triglycerides have been documented in some patients treated with these drugs.

If the elevation in lipid levels is modest, measures such as dietary modification and exercise may be tried first. Omega-3 fish oils may also be beneficial in reducing modestly-elevated serum triglycerides.

In refractory cases, or where there is extreme isolated hypertriglyceridaemia, a fibrate should be used.

In addition, patients with HIV disease may also have elevated serum lipid levels due to familial hyperlipidaemia.

[Q: 3999] OnExamination 2012 - Infectious disease

A 15-year-old female is a close contact of a student who has developed meningitis C. The

last contact she had with her friend was two days ago when her friend developed headache.

She has not received any previous vaccination for meningitis.

What is the most appropriate action for this girl?

- 1- No treatment is required and the girl can be reassured
- 2- She should receive the meningococcal A and C vaccination only
- 3- She should receive the meningococcal A and C vaccination plus rifampicin
- 4- She should receive meningococcal immunoglobulin only
- 5- Treat with rifampicin only

Answer & Comments

Answer: 3- She should receive the meningococcal A and C vaccination plus rifampicin

This girl runs a reasonably high risk of developing meningitis and should receive meningitis C vaccination together with rifampicin.

Antibiotics used for chemoprophylaxis are rifampicin, minocycline, spiramycin, ciprofloxacin and ceftriaxone. More here

Guidelines and Advice - Meningococcal

[Q: 4000] OnExamination 2012 - Infectious disease

A 17-year-old male presented with a widespread maculopapular rash. He had been prescribed amoxicillin for exudative tonsillitis.

What is the most likely diagnosis?

- 1- Acute HIV infection
- 2- Cytomegalovirus infection
- 3- Infectious mononucleosis
- 4- Parvovirus infection

5- Streptococcal infection

Answer & Comments

Answer: 3- Infectious mononucleosis

This patient has the typical features of glandular fever and this is confirmed by the typical rash following the introduction of amoxicillin.

This rash is considered almost pathognomonic of glandular fever and will subside following withdrawal of amoxicillin.

There are no other features in this patient's history to suggest an alternative diagnosis.

[Q: 4001] OnExamination 2012 - Infectious disease

A 25-year-old, previously healthy, woman has worsening fatigue with dyspnoea, palpitations, and fever over the past one week.

Her vital signs on admission to the hospital show temperature 38.9°C, respiratory rate 30/min, pulse 105 bpm and BP 95/65 mmHg. Her heart rate is irregular.

An ECG shows diffuse ST-T segment changes. A chest x ray shows mild cardiomegaly. An echocardiogram shows slight mitral and tricuspid regurgitation, but no valvular vegetations. Her troponin I is 12 ng/mL (<0.04).

She recovers over the next two weeks with no apparent sequelae.

Which of the following laboratory test findings best explains the underlying aetiology for these events?

- 1- ANCA titre of 1:80
- 2- Anti-streptolysin O titre of 1:512
- 3- Blood culture positive for streptococcus, viridans group
- 4- Coxsackie B serologic titre of 1:160
- 5- Total serum cholesterol of 9.6 mmol/l

Answer & Comments

Answer: 4- Cocksackie B serologic titre of 1:160

She has findings that suggest myocarditis, and this is supported by the temperature, echo findings and markedly raised troponin.

Myocarditis can have features similar to cardiomyopathy and the mild valvular disease is quite compatible.

One of the most likely organisms is Cocksackie B virus.

[Q: 4002] OnExamination 2012 - Infectious disease

A patient is planning to travel through the southern states of America but is worried about West Nile virus.

Which of the following statements regarding West Nile virus is correct?

- 1- Infection is non-fatal
- 2- Is a member of the arbovirus family
- 3- May be associated with poliomyelitis-like paralysis
- 4- Transplacental transmission does not occur
- 5- Treatment with interferon is effective in West Nile virus encephalitis

Answer & Comments

Answer: 3- May be associated with poliomyelitis-like paralysis

West Nile virus is a Flavivirus of the Japanese encephalitis family. It is thought it is spread when a mosquito bites an infected bird and then bites a human. Few of those bitten develop symptoms and even fewer progress to severe disease.

West Nile virus can be spread via vertical transmission as well as blood transfusions and organ transplant.

If infected with the virus, there are generally three different outcomes:

Asymptomatic (estimated 90%)

A mild febrile syndrome known as West Nile fever or rarely

Neuro-invasive disease termed West Nile meningitis or encephalitis.

West Nile fever can present with several vague 'generally unwell' symptoms that tend to last three to six days such as:

Abdominal pain

Diarrhoea

Fever

Headache

Arthralgia

Nausea and vomiting

Rash

Sore throat

Lymphadenopathy.

The following symptoms are suggestive of West Nile encephalitis/meningitis and prompt medical attention is required:

Extrapyramidal signs:

Confusion and seizures

Loss of consciousness or coma

Muscle weakness

Stiff neck

Weakness of one arm or leg (a poliomyelitis-like paralysis).

Diagnosis can be via blood or cerebral spinal fluid serology for West Nile antibodies. More rapid techniques using polymerase chain reaction may be used.

Due to the viral nature of the infection the current best treatment is supportive. In general it has an excellent prognosis. For those rare cases with severe infection it may lead to brain damage and death.

Approximately 10% of patients with brain inflammation do not survive.

In 2003 there were 276 deaths attributed to West Nile virus.

Interestingly, West Nile Virus is endemic in the avian population. The deaths of large numbers of birds in an area may thus herald an imminent epidemic of West Nile virus.

[Q: 4003] OnExamination 2012 -
Neurology

A 27-year-old woman is suffering with headaches that have occurred daily for the past three months.

They occur at different times of the day and affect the frontal and occipital areas. She has no neck stiffness or rash. She does not have any visual symptoms.

She has noticed cramps and tingling in her lips and fingers associated with palpitations and a feeling of suffocation. She takes no medication.

She is concerned because her father died from glioblastoma 12 months ago.

What is the likely cause of her headaches?

- 1- Anxiety neurosis
- 2- Benign intracranial hypertension
- 3- Glioblastoma
- 4- Nelson's syndrome
- 5- Neurosarcoidosis

Answer & Comments

Answer: 1- Anxiety neurosis

This lady's symptoms fit with an anxiety neurosis. She has symptoms of anxiety, headache, hyperventilation (tetany and tingling) and palpitations, related to the stressor of her father's death. There are no 'red flags' which would warrant further investigations.

Benign intracranial hypertension (BIH) and glioblastoma would give her a tendency to produce a headache that worsens with coughing or sneezing and might be associated with visual symptoms.

Neurosarcoidosis can present with nerve palsies, deficiencies of the pituitary function or character changes/psychosis, but this presentation would be extremely atypical.

Nelson's syndrome occurs following bilateral adrenalectomy for Cushing's syndrome in patients who have an adrenocorticotrophic hormone secreting pituitary adenoma. Pre-operatively the patients have high cortisol levels, which reduce following adrenalectomy. This causes an increased production of corticotropin-releasing hormone, which can result in unchecked growth of the pituitary adenoma. In turn this causes pressure on surrounding structures and the secondary loss of other pituitary hormones - a combination termed Nelson's syndrome.

[Q: 4004] OnExamination 2012 -
Neurology

A 67-year-old man is referred as an emergency by his general practitioner.

The night before he attempted to smother his wife whilst he was fast asleep. The following day, whilst oblivious to the potentially dangerous situation, he reports remembering dreaming about fighting a bear. His father had experienced a similar event some years before being diagnosed with Parkinson's disease.

Which of the following is the most likely diagnosis?

- 1- Adult attention deficit hyperactivity disorder (ADHD)
- 2- Lewy body dementia
- 3- Night terrors
- 4- REM sleep behaviour disorder
- 5- Schizophrenia

Answer & Comments

Answer: 4- REM sleep behaviour disorder

Rapid eye movement (REM) sleep behaviour disorder, is a parasomnia manifested by vivid dreams associated with simple or complex motor behaviour during REM sleep. Polysomnography demonstrates increased

electromyographic tone and dream enactment. often associated with the violent re-enacting of dreams, occurs when the normal atonicity of REM sleep is lost.

There is an association with the later development of movement disorders and these can be predicted by a number of years. Parkinson's disease is increasingly linked with REM sleep behaviour disorder.

Making the situation safe is paramount but treatment with clonazepam is the intervention of choice. Counselling can also play a role.

[Q: 4005] OnExamination 2012 - Neurology

A 33-year-old woman with epilepsy presents with visual problems.

Examination reveals a constriction of visual fields to confrontation.

Which of the following may be responsible for her visual deterioration?

- 1- Gabapentin
- 2- Lamotrigine
- 3- Phenytoin
- 4- Sodium valproate
- 5- Vigabatrin

Answer & Comments

Answer: 5- Vigabatrin

Vigabatrin is associated with constricted visual fields and when detected therapy should be stopped.

[Q: 4006] OnExamination 2012 - Neurology

A 32-year-old woman presents with a left sided postural tremor, a shuffling gait, dysarthric speech, ataxia and difficulty swallowing.

Which is the most important initial test?

- 1- Caeruloplasmin levels
- 2- CT head scan
- 3- Dopamine levels
- 4- Genetic testing
- 5- Serum copper

Answer & Comments

Answer: 1- Caeruloplasmin levels

Wilson's disease is an autosomal recessive disease linked to the q14-21 region on chromosome 13.

It is associated with impaired biliary excretion of copper, and impaired incorporation of copper into caeruloplasmin, resulting in copper overloading of the brain and liver.

Common symptoms are:

Parkinsonism

Bulbar signs

Postural tremor

Movement disorders and

Ataxia, as well as

Psychiatric symptoms and

Liver failure.

The most useful screening test is plasma caeruloplasmin, with levels less than 20 mg/dL suggestive.

With regard to the options:

Caeruloplasmin levels is correct as it is the most appropriate screening test for Wilson's disease.

CT head scan is incorrect as it will often be normal.

Dopamine levels is incorrect as dopamine levels do not help the diagnosis.

Genetic testing is incorrect as it is not an initial test.

Serum copper is incorrect as serum copper levels may be normal (urinary copper normally high).

[Q: 4007] OnExamination 2012 - Neurology

A 60-year-old man presents with mobility problems.

On examination he has Lhermitte's phenomenon, is Romberg's positive, and has a wide-based gait that deteriorates on eye closure, absent ankle jerks and extensor plantars. He takes thyroxine for an underactive thyroid, no other medical problems.

He is concerned as he had an uncle who developed unsteadiness and ended up in a wheelchair.

Which of the following is the likely diagnosis?

- 1- Cervical spondylosis
- 2- Friedreich's ataxia
- 3- Multiple sclerosis
- 4- Subacute combined degeneration of the cord.
- 5- Under-replacement of thyroxine

Answer & Comments

Answer: 4- Subacute combined degeneration of the cord.

Subacute combined degeneration of the cord is secondary to B12 deficiency.

B12 deficiency is usually caused by pernicious anaemia, this may be associated with other autoimmune conditions.

Lhermitte's phenomenon is typically present in multiple sclerosis, but may also occur in sub-acute combined degeneration of the cord.

This man's gait disturbance and positive Romberg's sign point towards dorsal column damage.

Causes of absent ankle jerks and extensor plantars include B12 deficiency, HIV, spinal AVM, taboparesis, Friedreich's ataxia and cervical and lumbar spondylosis.

The family history is a red herring. His uncle may well have had Friedreich's ataxia, however, this usually presents by the age of 30.

A. Cervical spondylosis is not the correct answer. This can cause Lhermitte's phenomenon. Only if both cervical and lumbar spondylosis are present can spondylosis cause absent ankle jerks and extensor plantars.

B. Friedreich's ataxia is not the correct answer. This may be associated with absent ankle jerks and extensor plantars but usually presents by age 30.

C. Multiple sclerosis is not the answer. This can cause Lhermitte's phenomenon and extensor plantars but could not account for the lower motor neurone signs.

D. Subacute combined degeneration of the cord is the correct answer.

E. Under-replacement of thyroxine is not the correct answer. Hypothyroidism can cause ataxia but would not account for the other symptoms.

[Q: 4008] OnExamination 2012 - Neurology

To difficulty in which of the following does optic ataxia refer?

- 1- Controlling hand-eye coordination
- 2- Moving the eyes
- 3- Seeing colours
- 4- Seeing objects
- 5- Shifting gaze

Answer & Comments

Answer: 1- Controlling hand-eye coordination

Shifting gaze is the problem of optic apraxia.

Both optic ataxia and optic apraxia together with simultagnosia are referred to as Balint's syndrome.

Difficulty seeing colours is achromatopsia.

Seeing objects can be due to retinal or occipital lesions, or parietal if certain objects such as faces cannot be identified.

[Q: 4009] OnExamination 2012 - Neurology

Cerebral malaria is caused by which of the following?

- 1- Plasmodium knowlesi
- 2- Plasmodium falciparum
- 3- Plasmodium malariae
- 4- Plasmodium vivax
- 5- Plasmodium yoelii

Answer & Comments

Answer: 2- Plasmodium falciparum

Of the Plasmodium species, only Plasmodium falciparum invades the central nervous system, causing cerebral malaria.

The neuropathology of cerebral malaria consists of diffuse cerebral swelling, widespread small-ring haemorrhages located in the subcortical white matter of the cerebral hemispheres, and plugging of cerebral capillaries and venules by parasitised erythrocytes; pigmentation with haemozoin is quite typical.

Focal neurologic deficits are relatively uncommon in cerebral malaria and are usually caused by a cerebral infarct due to arterial thrombosis occurring during the acute phase of the disease.

[Q: 4010] OnExamination 2012 - Neurology

A 72-year-old man comes to the neurology clinic with his wife. He is driving her mad as almost every night when he tries to go to bed he feels that something is crawling over his legs and he has an irresistible urge to scratch, rub or move them, and eventually has to get up and pace around the room.

He has no significant past medical history, apart from essential hypertension for which he takes ramipril 10 mg per day.

On examination his blood pressure is 139/73 mmHg, his pulse is 70 and regular and he has no murmurs. Respiratory, abdominal and neurological examinations are entirely normal.

Investigations show:

Haemoglobin 11.8 g/dl (13.5-17.7)

White cells $4.9 \times 10^9/L$ (4-11)

Platelets $230 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 122 $\mu\text{mol/l}$ (79-118)

Glucose 4.9 mmol/l (<5.5)

Which of the following is the most appropriate treatment?

- 1- Baclofen
- 2- L-dopa
- 3- Oxycodone
- 4- Ropinirole
- 5- Sodium valproate

Answer & Comments

Answer: 4- Ropinirole

This patient's history is typical for restless legs syndrome.

Dopamine agonists such as ropinirole are the treatment of choice, with anti-convulsants

such as sodium valproate being effective second line agents. Whilst opiates may be used, they are generally avoided due to long term tolerance.

Secondary restless legs syndrome may be seen in those with:

Diabetes mellitus

Anaemia

Chronic renal failure.

Symptoms can improve with correction of anaemia or control of blood sugar.

The associated sleep disturbance can have a significant negative effect on the quality of life.

[Q: 4011] OnExamination 2012 - Neurology

A 29-year-old woman comes to the clinic because she is concerned that her left pupil is abnormally large. Her boyfriend noticed it and suggested she should see the doctor.

She has no past medical history of note, apart from an episode of shingles a few months earlier, and takes the oral contraceptive pill as her only medication. On further questioning she admits to unprotected sexual intercourse on two to three occasions over the past three to four years.

On examination her left pupil is clearly larger than the right. It hardly reacts to light at all, but does accommodate to near vision. You notice that re-dilatation is very slow however. Her BP is normal at 132/72 mmHg, and general physical examination is unremarkable.

How best can you confirm the diagnosis?

- 1- Chest x ray
- 2- Lumbar puncture
- 3- MRI brain
- 4- Reaction to weak miotic eye drops

5- Syphilis serology

Answer & Comments

Answer: 4- Reaction to weak miotic eye drops

This history is typical of an Adie's tonic pupil, which is characteristically seen in young women, and may occur after an episode of zoster infection.

At the beginning of the condition the pupil is large, but over time becomes small and poorly reactive. Slit lamp examination may reveal small worm like contractions of the iris, but the usual diagnostic test is to use weak pilocarpine eye drops, which induce vigorous pupil contraction on the affected side, but only weak contraction of the pupil on the unaffected side.

In adults it tends to be a benign condition and is simply observed, however infants are usually referred because of an association with familial dystonias.

[Q: 4012] OnExamination 2012 - Neurology

A 56-year-old male with diabetes presents with a two day history of weakness of the left foot being aware of a feeling of dragging the toes along the floor when walking.

He has been diabetic for two years and on previous annual review no abnormalities were noted.

On examination he is unable to dorsiflex his left foot together with eversion of the foot. The right foot is unaffected. Plantar flexion and inversion are normal.

Which sensory abnormality would you expect to find in association with this motor defect?

- 1- No associated sensory loss
- 2- Sensory loss over the big toe
- 3- Sensory loss over the entire foot to the ankle.

- 4- Sensory loss over the lateral part of the leg and dorsum of the foot
- 5- Sensory loss over the plantar aspect of the foot

Answer & Comments

Answer: 4- Sensory loss over the lateral part of the leg and dorsum of the foot

This male with diabetes appears to have developed a mononeuropathy with the features compatible with a common peroneal nerve neuropathy. This would result in a loss of sensation over the dorsum of the foot and lateral part of the leg with sparing of the fifth toe.

Although you could argue that a peripheral neuropathy might be expected in this diabetic, the question specifically asks what defect would you expect to find with this neuropathy.

Also previously normal findings would argue against a sudden peripheral neuropathy.

[Q: 4013] OnExamination 2012 - Neurology

A 20-year-old female presents with seizures.

She is fit and healthy but had been unwell for three days prior to admission with flu-like symptoms.

The patient's friends tell you that prior to the seizure she had become confused and her behaviour had been out of character.

On examination the patient is post-ictal, with a fever of 39.1°C. She has a pulse of 100 bpm and a blood pressure of 130/71 mmHg. A CT head shows no abnormalities.

CSF examination shows no organisms, with a white cell count of 353/ mm³ (<5) mostly lymphocytes with a protein concentration of 2.3 g/l (0.29-1.98) and glucose of 3.2 mmol/l (3.0-6.0mmol/l).

What is the likely diagnosis?

- 1- Epilepsy
- 2- Herpes simplex encephalitis
- 3- Meningococcal meningitis
- 4- Pneumococcal meningitis
- 5- Viral meningitis

Answer & Comments

Answer: 2- Herpes simplex encephalitis

Herpes simplex encephalitis presents with:

Behavioural changes or psychiatric disturbance

Focal seizures

Fever and

Alteration in consciousness.

It has peaks of presentation in the young and old.

A computerised tomography (CT) scan of the brain may be normal, but a magnetic resonance imaging (MRI) may reveal the diagnosis.

Cerebrospinal fluid (CSF) shows a pleomorphic monocytois with raised protein, sometimes elevated red cells and a normal or low glucose.

A high index of suspicion should give you the diagnosis, and if in doubt, intravenous aciclovir will protect the patient whilst other avenues are being explored.

[Q: 4014] OnExamination 2012 - Neurology

A 69-year-old male presents with sudden onset weakness of his legs associated with urinary retention. Five years previously he was diagnosed with sigmoid colonic carcinoma which was surgically resected.

Examination revealed a flaccid paraparesis of the legs with absent tendon reflexes and plantar responses. Pinprick and temperature

sensations were absent to T12 level, but there was a relative sparing of light touch and joint position sensation.

What is the most likely diagnosis?

- 1- Anterior spinal artery occlusion
- 2- Intramedullary spinal cord metastasis
- 3- Spinal cord compression due to vertebral metastasis
- 4- T11/12 central disc prolapse
- 5- Transverse myelitis

Answer & Comments

Answer: 1- Anterior spinal artery occlusion

The lesion is involving the anterior two thirds of the spinal cord which spares light touch, vibration and position sense, but causes loss of pain and temperature sensation distally.

The diagnostic possibilities therefore include anterior spinal artery occlusion, which is rare, and intramedullary spinal cord metastasis.

The condition has developed quite suddenly, which is the key and supports a vascular event.

Intramedullary spinal cord lesions are also rare, and vertebral metastasis causing cord compression occurs more commonly; however the clinical signs suggest sparing of the dorsal columns.

[Q: 4015] OnExamination 2012 - Neurology

A 54-year-old male presents with progressive pins and needles and numbness in both feet which have deteriorated over the last six months.

He has a 10 year history of type 2 diabetes mellitus and had cervical spondylosis for which he underwent surgery eight years ago. He also confessed to drinking approximately 40 units of alcohol weekly.

On examination he had a mild bilateral weakness of foot dorsiflexion, both ankle reflexes were absent and plantar responses were flexor. There was absent sensation to light touch to mid-shin level with loss of joint position sensation in the toes and absent vibration sensation below the hips. He had a marked sensory ataxia and pseudoathetosis of upper limbs. He had no evidence of a retinopathy and urinalysis was normal.

What is the most likely diagnosis?

- 1- Alcohol-induced neuropathy
- 2- Central lumbar disc prolapse
- 3- Cervical cord compression
- 4- Diabetic peripheral neuropathy
- 5- Vitamin B₁₂ deficiency

Answer & Comments

Answer: 5- Vitamin B₁₂ deficiency

Diabetic peripheral neuropathy usually goes in parallel with retinopathy and nephropathy.

It is also slowly progressive and affects mainly the spinothalamic pathway.

Alcohol induced peripheral neuropathy is also slowly progressive and affects mainly spinothalamic pathway.

Vitamin B₁₂ deficiency usually causes a more rapidly progressive neuropathy with dorsal column involvement (joint position and vibration involvement with sensory ataxia and pseudoathetosis of upper limbs).

[Q: 4016] OnExamination 2012 - Neurology

A 16-year-old girl is noted to have persistent polyuria in excess of 4 litres per day whilst recovering from a head injury she sustained in a road traffic accident.

Investigations reveal:

Potassium 4.1 mmol/L (3.5-4.9)

Calcium 2.4 mmol/L (2.2-2.6)

Glucose 5.6 mmol/L (3.0-6.0)

Which one of the following is the most effective method of confirming the diagnosis?

- 1- Autoantibodies to vasopressin neurones
- 2- MRI of the hypothalamus and pituitary
- 3- Therapeutic trial of low dose DDAVP
- 4- Vasopressin concentration
- 5- Water deprivation test

Answer & Comments

Answer: 5- Water deprivation test

The history and confirmed polyuria are suspicious of diabetes insipidus (DI) which is not uncommon after head injury.

This can be confirmed with a water deprivation test where failure of urine concentration would be expected.

An MRI of the pituitary and hypothalamus may show no abnormality but would be undertaken after the diagnosis of DI is confirmed.

Similarly anterior hormone assessment would also be undertaken after the diagnosis is confirmed.

A therapeutic trial of DDAVP is only appropriate if the diagnosis of DI is confirmed as primary polydipsia can also be a feature of trauma and in these circumstances DDAVP may precipitate hyponatraemia.

Autoantibodies to antidiuretic hormone (ADH) neurones are irrelevant.

[Q: 4017] OnExamination 2012 - Neurology

A 38-year-old woman is referred to the casualty department with bilateral weakness in her legs. She also complains of general malaise.

Three weeks previously she had returned from a four week tour of Eastern Europe.

On examination she appeared unwell and was pyrexial (38.9°C). She had large palpable cervical lymph nodes bilaterally. Her pharynx was inflamed with areas of exudate on the pharyngeal wall.

Neurological examination revealed global weakness of both legs and absent reflexes.

What is the most likely diagnosis?

- 1- Cytomegalovirus infection
- 2- Diphtheria
- 3- Epstein-Barr virus infection
- 4- Hodgkin's disease
- 5- Streptococcal tonsillitis

Answer & Comments

Answer: 2- Diphtheria

The breakdown of healthcare services in the former USSR was associated with a major resurgence of diphtheria.

Pharyngeal diphtheria presents with:

Fever

Sore throat

Cervical lymphadenopathy and

An adherent, grayish pharyngeal membrane.

The diphtheria toxin causes cardio- and neurotoxicity.

Treatment consists of antibiotic therapy and diphtheria antitoxin.

[Q: 4018] OnExamination 2012 - Neurology

A 30-year-old female presents with weight gain, some hair loss and a tremor six months after commencing single drug treatment.

Which one of the following drugs is most likely to be responsible for her symptoms?

- 1- Carbamazepine
- 2- Lamotrigine
- 3- Phenytoin
- 4- Sodium valproate
- 5- Topiramate

Answer & Comments

Answer: 4- Sodium valproate

Sodium valproate is associated with:

Weight gain

Tremor

Hair loss

Teratogenicity

Polycystic ovary disease.

Lamotrigine is associated with skin rash (and Stevens-Johnson syndrome in severe cases).

Topiramate is associated with:

Renal stones

Weight loss

Cognitive impairment

Tingling in extremities.

Phenytoin is associated with:

Peripheral neuropathy

Cerebellum syndrome

Acne

Hirsutism

Gingival hypertrophy

Hypocalcaemia.

[Q: 4019] OnExamination 2012 - Neurology

A 50-year-old woman is referred with a two week history of difficulty walking and weakness in her arms.

On examination, there was proximal and distal limb weakness which was more marked in the legs than the arms. All tendon reflexes were absent and the plantar responses were flexor. There was no sensory loss.

Blood pressure in the supine position was 140/78 mmHg (lying) and was 110/70 mmHg on standing.

What is the most likely diagnosis?

- 1- Cervical cord compression
- 2- Guillain-Barré syndrome
- 3- Myasthenia gravis
- 4- Poliomyelitis
- 5- Polymyositis

Answer & Comments

Answer: 2- Guillain-Barré syndrome

This is a classical presentation of Guillain-Barre with the gradual development of ascending weakness with autonomic involvement.

[Q: 4020] OnExamination 2012 - Neurology

A 70-year-old woman presented with a relatively short history of headaches and episodic impairment of consciousness.

What is the most likely cause?

- 1- Alzheimer-type dementia
- 2- Chronic subdural haematoma
- 3- Creutzfeldt-Jakob disease
- 4- Depressive stupor
- 5- Normal pressure hydrocephalus

Answer & Comments

Answer: 2- Chronic subdural haematoma

This is the classical presentation of subdural haematoma.

Headache, drowsiness and confusion are common and often fluctuate.

Both dementia and depressive stupor (immobile, mute, unresponsive but fully conscious) are not associated with impaired consciousness.

Normal pressure hydrocephalus is characterised by dementia, apraxia and urinary incontinence.

[Q: 4021] OnExamination 2012 - Neurology

Which of the following features is characteristic of myasthenia gravis?

- 1- Diplopia
- 2- Equal sex incidence
- 3- Fasciculation
- 4- Lid lag
- 5- Loss of pupillary reflexes

Answer & Comments

Answer: 1- Diplopia

Myasthenia gravis is more common in females (it is an autoimmune disease).

The most common features include ptosis, diplopia and ophthalmoplegia.

It is a neuromuscular disorder and therefore does not cause any lower motor neuron signs such as fasciculations, wasting, and loss of reflexes.

Pupils are always normal.

Lid lag is a feature of thyroid eye disease.

[Q: 4022] OnExamination 2012 - Neurology

By which of the following is a demyelinating polyneuropathy typically caused?

- 1- Diabetes
- 2- Excessive alcohol

- 3- Hereditary motor sensory neuropathy
- 4- Renal failure
- 5- Vitamin B₁₂ deficiency

Answer & Comments

Answer: 3- Hereditary motor sensory neuropathy

The differential diagnosis of demyelinating neuropathy includes:

Hereditary motor sensory neuropathy (Charcot-Marie-Tooth disease)

Refsum's disease

Guillain-Barre syndrome

Chronic inflammatory demyelinating polyneuropathy (CIDP)

Paraprotein-related disorder

Leukodystrophies.

An axonal polyneuropathy may be caused by:

Amiodarone

Diabetes

Alcohol

Vitamin deficiencies

Renal failure.

[Q: 4023] OnExamination 2012 - Neurology

A 17-year-old male has been diagnosed with schizophrenia four weeks ago.

He was started on haloperidol. Two weeks later he was found confused and drowsy.

On examination he was pyrexial (40.7°C), rigid with blood pressure of 200/100 mmHg.

Which of the following treatments will you initiate?

- 1- Aciclovir
- 2- Cefuroxime

- 3- Dantrolene
- 4- Diazepam
- 5- Phenytoin

Answer & Comments

Answer: 3- Dantrolene

Neuroleptic malignant syndrome is the most likely diagnosis.

Its major features are:

Rigidity

Altered mental state

Autonomic dysfunction

Fever and

High creatinine kinase.

It is usually caused by potent neuroleptics.

The treatments of choice are dantrolene and bromocriptine.

Withdrawal of neuroleptic treatment is mandatory.

Rhabdomyolysis and acute renal failure are potential complications.

[Q: 4024] OnExamination 2012 - Neurology

A 40-year-old man presents with a two year history of intermittent strictly unilateral headaches.

The pain is excruciatingly severe. It is located around the orbital region. The headache usually lasts 45-60 minutes. It usually occurs in the early hours of the morning.

There is associated ptosis and lacrimation on the side of the headache.

Which of the following is the most likely diagnosis?

- 1- Cluster headaches
- 2- Giant cell arteritis

- 3- Migraine
- 4- Tension type headache
- 5- Trigeminal neuralgia

Answer & Comments

Answer: 1- Cluster headaches

Cluster headache has three important features:

Trigeminal distribution pain

Ipsilateral cranial autonomic features and

The striking tendency to circadian and circannual periodicity.

It is commoner in men (5:1).

It is associated with:

Lacrimation

Rhinorrhoea

Conjunctival injection

Ptosis and

Miosis.

The common age of onset is the third or fourth decade of life.

[Q: 4025] OnExamination 2012 - Neurology

A 20-year-old female presents with acute onset of left foot drop.

Examination reveals weakness of ankle dorsiflexion and eversion. There is a small area of sensory loss in the first web space. Reflexes were all present and plantar flexor.

Which of the following nerves is likely to be involved?

- 1- Common peroneal nerve
- 2- Femoral nerve
- 3- Inferior gluteal nerve
- 4- Sciatic nerve

5- Tibial nerve

Answer & Comments

Answer: 1- Common peroneal nerve

Peroneal neuropathy usually presents with acute foot drop.

The foot and ankle weakness on neurological examination is restricted to ankle and toe dorsiflexion and ankle eversion.

Ankle reflex (tibial nerve mediated) and knee reflex (femoral nerve mediated) are intact.

Sensory involvement may include the lower two thirds of the lateral leg and dorsum of foot.

[Q: 4026] OnExamination 2012 - Neurology

A 60 year-old male who had been admitted a month ago with a left hemiparesis due to a right thalamic infarction re-presents with painful subluxation of his left shoulder.

Two weeks later he develops severe, constant burning left shoulder pain which radiates down his arm. He found no relief from paracetamol.

Which of the following is most likely to relieve his pain?

- 1- Depo-Medrone injection into the shoulder
- 2- Diclofenac
- 3- Dihydrocodeine
- 4- Gabapentin
- 5- Tramadol

Answer & Comments

Answer: 4- Gabapentin

The description of the pain (burning, radiating) supports the diagnosis of neuropathic pain.

Thalamic infarcts commonly cause late-onset of severe neuropathic pain weeks to months after the stroke. The pain is intractable to analgesics.

The treatment of choice for neuropathic pain is amitriptyline/gabapentin.

There are randomised controlled trials which support their value in neuropathic pain.

[Q: 4027] OnExamination 2012 - Neurology

The incidence of Down's syndrome in children born to women aged less than 30 years is approximately which of the following?

- 1- 1:500
- 2- 1:1000
- 3- 1:5000
- 4- 1:10000
- 5- 1:15000

Answer & Comments

Answer: 2- 1:1000

The incidence is roughly 1 in 1200 births for woman less than 30 and this incidence can rise to 1 in 60 by the age of 42.

Maternal age also affects the incidence of hydrocephalus, anencephaly and other chromosomal disorders.

[Q: 4028] OnExamination 2012 - Neurology

A 71-year-old woman consults you.

She has recently been started on an antihypertensive but she has noticed a dry mouth and dizziness on standing.

Which medication is it likely to be?

- 1- Doxazosin
- 2- Enalapril
- 3- Isosorbide mononitrate

4- Nicardipine

5- Olmesartan medoxomil

Answer & Comments

Answer: 1- Doxazosin

Doxazosin is an alpha-adrenoceptor blocker. It can cause rapid reduction in BP and therefore requires gradual introduction and up-titration. Its side effects include dry mouth, syncope, drowsiness, oedema and gastrointestinal (GI) disturbances.

Enalapril and other angiotensin-converting enzyme (ACE) inhibitors most commonly cause a dry cough and postural hypotension. They can also cause angioedema and hyperkalaemia.

The nitrate class of drugs commonly causes headache and dizziness.

Nicardipine and other calcium channel blockers may cause peripheral oedema, headache, flushing and palpitations.

Olmesartan, an angiotensin 2 blocker has a similar side effect profile to ACEi except usually milder and does not cause a dry cough, as it does not affect bradykinin synthesis.

[Q: 4029] OnExamination 2012 - Neurology

You are called to see a man in the Emergency department who has been in a road traffic accident. His memory of events is poor but he thinks he banged his head. His main complaint now is of extreme pain in his right eye.

On examination he has reduced visual acuity (counting fingers only), proptosis and complete ophthalmoplegia of his right eye. You notice that the eye is injected, chemotic and on closer inspection appears to be pulsating.

Which of the following is the most likely diagnosis?

1- Acute glaucoma

2- Blow-out fracture

3- Carotidocavernous fistula

4- Cavernous sinus thrombosis

5- Retinal haemorrhage

Answer & Comments

Answer: 3- Carotidocavernous fistula

A carotidocavernous fistula is a high pressure shunt of blood between the intracavernous carotid artery and the cavernous sinus.

It is usually traumatic and may occur secondary to open or closed head trauma.

Patients usually complain of pain in the eye.

The most striking sign is pulsatile proptosis. Patients also have palsies of the IIIrd, IVth and Vth nerve palsies, injection and chemosis due to raised episcleral venous pressure. Those who know to listen for it will also hear an orbital bruit.

Regarding the options :

A. Acute glaucoma is not the answer. This causes visual loss and a painful red eye but does not usually follow trauma. It is not associated with ophthalmoplegia, proptosis or visible pulsations.

B. A blow-out fracture is not the answer. This is a fracture of the walls or floor of the orbit. It may cause diplopia in upgaze due to trapping of the eye muscles but would not typically cause the other symptoms.

C. See above.

D. Cavernous sinus thrombosis is not the answer. This may produce ophthalmoplegia and proptosis, does not usually follow trauma and would not cause the pulsations.

E. Retinal haemorrhage is not the answer. This causes painless visual loss but would not cause the other symptoms.

[Q: 4030] OnExamination 2012 - Neurology

A 23-year-old woman presents to the clinic after waking up with difficulty seeing. She reports no past medical history and is currently on no medication.

On examination she has decreased visual acuity of the left eye and red desaturation. She is concerned that she has multiple sclerosis.

You explain that this is not by definition multiple sclerosis.

What is her chance of developing multiple sclerosis?

- 1- 25%
- 2- 33%
- 3- 50%
- 4- 75%
- 5- 100%

Answer & Comments

Answer: 3- 50%

'The cumulative probability of developing MS by 15 years after onset of optic neuritis was 50% (95% confidence interval, 44%-56%) and strongly related to presence of lesions on a baseline non-contrast-enhanced magnetic resonance imaging (MRI) of the brain. Twenty-five percent of patients with no lesions on baseline brain MRI developed MS during follow-up compared with 72% of patients with 1 or more lesions. After 10 years, the risk of developing MS was very low for patients without baseline lesions but remained substantial for those with lesions. Among patients without lesions on MRI, baseline factors associated with a substantially lower risk for MS included male

sex, optic disc swelling, and certain atypical features of optic neuritis'.

Reference:

The Optic Neuritis Study Group

Arch Neurol. 2008;65(6):727-732.

[Q: 4031] OnExamination 2012 - Neurology

A 30-year-old woman presents to the emergency room after an episode of transient left sided weakness lasting 30 minutes.

She reports that she was driving at the time and describes a white zigzag before developing a headache. She then describes a descending numbness and weakness on the left-side of her body. She stopped the car and called an ambulance. On arrival at the hospital her blood pressure was 130/80 mmHg, pulse was regular at 90 beats per minute. She is alert and orientated.

She follows commands, has full strength in her limbs and symmetric reflexes and normal tone. Her cranial nerves are intact and fundoscopy is unremarkable. Visual fields are full on direct confrontation and the eye movements are intact. There is a family history of stroke in her mother, and her sister has migraines. Her past medical history is notable for migraines and hyperthyroidism.

What is the most likely explanation?

- 1- Cerebrovascular accident
- 2- Complicated migraine
- 3- Confusion migraine
- 4- Migraine with aura
- 5- Transient ischemic attack

Answer & Comments

Answer: 2- Complicated migraine

A confusional migraine involves alteration in sensorium rather than limb involvement.

A transient ischemic attack is a possibility however given the history of migraines and

age the most likely diagnosis is complicated migraine.

The presentation does not fit for a stroke.

A migraine with aura does not present with unilateral weakness.

[Q: 4032] OnExamination 2012 - Neurology

A 4-year-old girl presents to the office with her mother. The mother reports that the child is minimally interactive with others.

On examination the child is of short stature. She sits quietly rubbing her hands together and appears disinterested in the visit.

What is the most likely diagnosis?

- 1- Autism spectrum disorder
- 2- Rett syndrome
- 3- Turner's syndrome
- 4- Emery-Dreifuss muscular dystrophy
- 5- Absence seizure

Answer & Comments

Answer: 2- Rett syndrome

A and B. Although similar to autism, Rett syndrome presents with classic hand wringing.

C. Turner's syndrome is an X linked disorder with short stature associated with attention deficit hyperactivity disorder (ADHD) and learning disabilities.

D. Emery-Dreifuss muscular dystrophy affects skeletal and cardiac muscle and presents with progressive weakness.

E. Absence seizures can be associated with automatisms such as lip smacking.

[Q: 4033] OnExamination 2012 - Neurology

A 29-year-old woman who has a history of

epilepsy comes to the clinic complaining of worsening hair loss. She has generalised tonic clonic seizures and has been taking her medication for the past two to three years. Her epilepsy is currently well controlled.

Which of the following medications is she most likely to be taking?

- 1- Carbamazepine
- 2- Gabapentin
- 3- Lamotrigine
- 4- Valproate
- 5- Vigabatrin

Answer & Comments

Answer: 4- Valproate

Up to 12% of patients taking sodium valproate report significant hair loss in clinical trials. Of course, as hair loss is relatively common, other causes of hair loss should be excluded before changing anti-epileptic medication.

Carbamazepine hair loss is recognised, but is only seen in around 6% of patients.

Limited data suggest zinc or selenium supplementation may be associated with reduced hair loss, but these data are somewhat controversial.

[Q: 4034] OnExamination 2012 - Neurology

A 26-year-old female is admitted to ICU with severe asthma.

She is ventilated for one week and receives IV co-amoxiclav/clarithromycin, magnesium, prednisolone, sedatives and muscle relaxants.

She improves gradually but two days after stopping muscle relaxants she still is unable to be weaned from ventilatory support.

On examination, she is alert but has flaccid weakness of all limbs.

Which of the following is the likely diagnosis?

- 1- Critical illness polyneuropathy
- 2- Guillain-Barré syndrome
- 3- Hypermagnesaemia
- 4- Prolonged neuromuscular blockade
- 5- Steroid induced myopathy

Answer & Comments

Answer: 4- Prolonged neuromuscular blockade

The history suggests prolonged neuromuscular junction (NMJ) blockade which may be exacerbated by both corticosteroids and magnesium.

This condition was originally described with suxamethonium due to hereditary reductions in plasma cholinesterase activity.

However, drugs and electrolyte abnormalities may exacerbate this.

[Q: 4035] OnExamination 2012 - Neurology

A 66-year-old male presents with a sudden onset of ataxia, vomiting and headache, followed by increasing drowsiness.

What is the most likely diagnosis?

- 1- Acute cerebellar haemorrhage
- 2- Acute subdural haemorrhage
- 3- Frontal subdural empyema
- 4- Herpes simplex encephalitis
- 5- Pituitary apoplexy

Answer & Comments

Answer: 1- Acute cerebellar haemorrhage

Acute cerebellar infarct or haemorrhage is associated with acute onset of ataxia, headache and vomiting and eventually drowsiness and coma due to the development of obstructing hydrocephalus.

Early computerised tomography (CT) brain scan and close observation are essential in the management of acute cerebellar haemorrhage.

[Q: 4036] OnExamination 2012 - Neurology

A 55-year-old male presents with a history of low back pain and sciatica. The pain radiates to the little toe, the ankle reflex is absent and the patient has difficulty in everting the foot.

Which nerve root is likely to be trapped?

- 1- L3
- 2- L4
- 3- L5
- 4- S1
- 5- S2

Answer & Comments

Answer: 4- S1

The root supply to the peroneal muscles (which control eversion of the foot and which also participate in the reflex arc of the ankle jerk reflex) is S1 via the tibial and superficial peroneal nerves.

The sensory dermatome of the S1 root gives innervation to the postero-lateral aspect of the leg and foot down to and including the little toe and sole of foot.

[Q: 4037] OnExamination 2012 - Neurology

Which of the following statements regarding phenylketonuria is correct?

- 1- Inheritance is X linked recessive
- 2- Is classically due to deficiency of tyrosine hydroxylase
- 3- Mental retardation does not occur if the patient adheres to a phenylalanine free diet

- 4- Serum tyrosine levels are typically low
- 5- Urinary phenylalanine metabolites are typically high

Answer & Comments

Answer: 5- Urinary phenylalanine metabolites are typically high

Phenylketonuria (PKU) is the result of hyperphenylalaninaemia. It is autosomal recessive, with a prevalence of 1:10-20,000 live births.

Phenylalanine is an essential amino acid. Dietary phenylalanine is not utilised for protein synthesis, but is normally degraded via the tyrosine pathway. Failure of this results in other metabolites that cause brain damage.

Deficiency of phenylalanine hydroxylase (chromosome 12) or of the cofactor tetrahydrobiopterin (genes on chromosome 10 and 4) causes accumulation of phenylalanine in body fluids. The affected infant is usually normal at birth, and although blood phenylalanine levels may rise as early as four hours after birth, mental retardation develops gradually, and may not be apparent for a few months.

About 25% of infants have seizures, but over 50% have an abnormal EEG.

Microcephaly, prominent maxilla, growth retardation and wide-spaced teeth are found in untreated children.

Even with dietary treatment some degree of cognitive impairment is seen, and can vary from gross impairment or changes detected on cognitive tests.

Cerebral white matter changes are seen in older patients and may reflect a combination of late diagnosis and dietary indiscretion.

Diagnosis of classic PKU requires raised Phe levels, normal plasma tyrosine levels, increased urinary Phe metabolites and

normal cofactor (tetrahydrobiopterin) concentrations.

[Q: 4038] OnExamination 2012 - Neurology

A 30-year-old lady who suffers from migraine complains that taking the recommended dose of paracetamol during an attack fails to relieve her headache. She has no other significant past medical history. She is a smoker of 15 cigarettes per day and also drinks alcohol 16 units per week.

Which of the following factors most likely explains the lack of efficacy of paracetamol in this lady?

- 1- Bacterial overgrowth
- 2- Delayed gastric emptying
- 3- First pass metabolism
- 4- p450 enzyme induction
- 5- p450 enzyme inhibition

Answer & Comments

Answer: 2- Delayed gastric emptying

'When salicylate absorption from effervescent aspirin tablets was studied during migraine, the rate of absorption was found to be reduced relative to that found in non-migrainous volunteers and in the same patients when headache-free. There is evidence that this reduced rate of absorption is caused by gastrointestinal stasis and reduced rate of gastric emptying. Patients in whom aspirin absorption was delayed were more likely to take longer to respond and to require additional treatment.' Clin Pharmacokinet. 1978 Jul-Aug;3(4):313-8. Metoclopramide may be useful in accelerating gastric emptying.

The same has also been shown with paracetamol absorption.

Br J Clin Pharmacol. 1984 Dec;18(6):867-71

[Q: 4039] OnExamination 2012 -
Neurology

A 40-year-old male presents to casualty with weakness and paraesthesia of the right arm and leg.

The symptoms developed 12 hours after the onset of a piercing left sided headache. There is no neck stiffness, but there is a pain in the left side of the neck and occiput. Kernig's sign is negative. The patient is afebrile, and blood results are normal.

What is the single best investigation of choice?

- 1- Contrast arteriography
- 2- CT head
- 3- Duplex scanning of the neck vessels
- 4- Lumbar puncture
- 5- MRI brain

Answer & Comments

Answer: 1- Contrast arteriography

Ischaemic neurological features (transient or completed strokes) are found in 30-80% of patients presenting with carotid artery dissection.

Pulsatile tinnitus is common, as well as syncope and amaurosis fugax.

Headache is commonly ipsilateral to the side of the carotid dissection, and recurrence of the headache suggests extension or recurrence of the dissection.

As it is the most accurate study and the current gold standard for diagnosis of carotid artery dissection, contrast arteriography should be strongly considered, if there is mono or hemiparesis with normal mental state, signs or history of major cervical trauma with abnormal neurology, or basilar skull fracture in a patient with altered mental status.

Obviously in practice many trusts will require a CT head first. Additionally in the absence of arteriography, duplex scanning or MRI with MRA may be considered the next best tests.

However limitations of duplex scanning include difficulties of scanning the distal internal carotid artery, detecting emboli, and evaluating intracranial arteries.

The combination of MRI and MRA is more reliable in detecting dissection than either modality alone.

Lumbar puncture results may be misleading, as xanthochromia may occur when a haematoma propagates. This rare finding may lead to a misdiagnosis of subarachnoid haemorrhage and failure to perform further carotid workup.

[Q: 4040] OnExamination 2012 -
Neurology

A 47-year-old patient with diabetes is referred from the Emergency department complaining of dizziness and vomiting.

On examination he is alert and orientated, his pulse is 80 irregularly irregular and BP 160/90 mmHg. There is nystagmus on left lateral gaze and his speech is slurred. On examination of the limbs you note intention tremor and past pointing. He is ataxic when mobilised.

What is the likely diagnosis?

- 1- Brainstem infarction.
- 2- Cerebellar CVA
- 3- Sub-acute combined degeneration of the cord
- 4- Viral labyrinthitis
- 5- Wernicke's encephalopathy

Answer & Comments

Answer: 2- Cerebellar CVA

This man has a history of vertigo and the clinical signs of nystagmus. Slurred speech,

intention tremor and past pointing, as well as ataxia, suggest the cerebellum as the site of injury.

This man also has risk factors for cerebrovascular disease including atrial fibrillation and hypertension.

Labyrinthitis would not produce cerebellar signs despite being associated with nystagmus.

In Wernicke's encephalopathy, you would expect confusion with ophthalmoplegia and ataxia.

Sub-acute combined degeneration of the cord is associated with posterior column signs, loss of vibration sensation and a positive Romberg's test.

Brainstem signs would be expected with a brainstem CVA and impaired conscious level.

[Q: 4041] OnExamination 2012 - Neurology

An 85-year-old woman with diabetes mellitus presented with sudden onset of wild flinging movements of the left arm which disappeared during sleep.

What is the most likely explanation?

- 1- Contralateral subthalamic nucleus infarction
- 2- Focal motor seizures
- 3- Hypoglycaemia
- 4- Ipsilateral caudate nucleus infarction
- 5- Ipsilateral cerebellar infarction

Answer & Comments

Answer: 1- Contralateral subthalamic nucleus infarction

This is hemiballismus, and in a diabetic patient is likely to be due to a vascular event in the contralateral subthalamic nucleus.

[Q: 4042] OnExamination 2012 - Neurology

A 68-year-old female presents with a four month history of weight loss, headaches and had recently developed double vision.

Six years previously she underwent a right mastectomy for breast carcinoma and remains on treatment with tamoxifen.

Examination revealed tenderness over the temporal region and a left sixth nerve palsy.

Her chest x ray was reported as normal, but she had an ESR of 100 mm/hr (0-30) and her Hb was 10.8 g/dL (11.5-16.5).

Which of the following statements is correct?

- 1- An isotope bone scan should be performed
- 2- An urgent CT brain scan is required
- 3- She should be given diamorphine
- 4- She should be treated with prednisolone immediately
- 5- She should have a lumbar puncture

Answer & Comments

Answer: 4- She should be treated with prednisolone immediately

Giant cell arteritis is a clinical emergency.

High doses of steroids (1mg/kg) should be initiated as soon as possible to prevent visual loss, which is usually irreversible.

Typical clinical features include:

Headache

Tender non-pulsatile temporal artery

Systemic symptoms of lethargy, weight loss, pyrexia, jaw claudication, visual loss and diplopia (various ophthalmoplegias are recognised in association with GCA).

It is also associated with polymyalgia rheumatica.

Sometimes the vignette will give you too many details. Your task is to decide what is important. For example breast ca. could raise the ESR and therefore put you off the idea that this is TA. The point is to realise that this is an important consideration not to miss as otherwise the patient could go blind and should be given steroids, followed by biopsy.

[Q: 4043] OnExamination 2012 - Neurology

A 28-year-old female, three days post-partum, develops severe headache associated with seizures.

During her pregnancy her blood pressure had been mildly elevated in the third trimester.

On examination, she had a GCS of 15 but was slightly confused and drowsy. Her temperature was 37.5°C, she had mild nuchal rigidity but neurological examination was otherwise normal.

What is the most likely diagnosis?

- 1- Bacterial meningitis
- 2- Cortical vein thrombosis
- 3- Eclampsia
- 4- Intracerebral haemorrhage
- 5- Subarachnoid haemorrhage

Answer & Comments

Answer: 2- Cortical vein thrombosis

Post-partum period is a risk factor of cortical vein and sinus thrombosis.

It typically presents with headache, seizures and focal neurological deficit two to three weeks postpartum (but is also seen earlier).

Other clinical presentations include a benign intracranial hypertension (BIH) type of picture (papilloedema, visual disturbances and headaches) or a subacute encephalopathic picture. Thrombophilia screen should be performed.

Eclampsia typically improves following delivery but despite this 1/3 of seizures occur in the four days following delivery, the seizures can in fact occur antepartum, intrapartum, or postpartum. If a seizure does occur postpartum, it usually occurs within the first 24 hours after delivery.

Although eclampsia would be in the differential diagnosis in this case, nuchal rigidity is not a typical feature which points more to the direction of cortical vein thrombosis.

[Q: 4044] OnExamination 2012 - Neurology

A 26-year-old man presented with a 24 hour history of blurred vision in the left eye and mild left frontal headache. He had a ten year history of diabetes mellitus.

Examination of the left eye revealed a central scotoma.

What is the most likely diagnosis?

- 1- Central retinal artery occlusion
- 2- Diabetic retinopathy
- 3- Migraine
- 4- Optic neuritis
- 5- Pituitary tumour

Answer & Comments

Answer: 4- Optic neuritis

Occlusion of the central retinal artery or one of its branches which supplies the macular region will result in almost immediate diminution or loss of visual acuity in the involved eye and is usually without pain.

In a young diabetic the aetiology is usually an embolus of the central retinal artery or one of its branches. However there is pain associated with this visual loss, namely headache.

Diabetes is a cause of optic neuritis which is usually associated with headache.

Retinopathy, per se, would not lead to an acute central scotoma unless there was acute bleeding from neovascularisation.

[Q: 4045] OnExamination 2012 - Neurology

A 63-year-old man presents with a three month history of tremor affecting his left arm.

In his past medical history he had suffered from a depressive psychosis for 10 years for which he had received intermittent chlorpromazine and amitriptyline but had not taken any therapy for the last four months. He describes that his two brothers also had tremors.

On examination he had a resting tremor of his left hand, with cogwheel rigidity of that arm and he had a mild generalised bradykinesia.

What is the most likely diagnosis?

- 1- Benign essential tremor
- 2- Drug-induced parkinsonism
- 3- Idiopathic Parkinson's disease
- 4- Multiple system atrophy
- 5- Wilson's disease

Answer & Comments

Answer: 3- Idiopathic Parkinson's disease

The most likely diagnosis is idiopathic Parkinson's disease due to the fact that the symptoms and signs are present only on the left side. Parkinson's disease is a common neurodegenerative disorder which selectively affects dopaminergic neurons of the substantia nigra, culminating in their destruction. After approximately 50% of the dopamine neurones, and 75-80% of striatal dopamine is lost patients start to exhibit the classical signs of bradykinesia, resting tremor

and rigidity. These signs are often unilateral initially.

Despite many years of research, the cause of Parkinson's disease is not fully understood. The relative contribution of genetic and environmental factors still remains unclear.

Neuroleptic-induced parkinsonism is usually bilateral and symmetrical.

Essential tremor does not cause rest tremor (it usually causes bilateral postural and action tremor).

It is unusual for Wilson's disease to present this late in life.

Multi-system atrophy is characterised by Parkinsonian features, cerebellar ataxia and autonomic dysfunction.

[Q: 4046] OnExamination 2012 - Neurology

A 69-year-old man is admitted with pain and numbness in his right foot following a right hip replacement.

In his past medical history he had been treated for lower backache by his GP.

On examination there was weakness of all movements at the right ankle, with absent right ankle jerk, and sensory impairment on the lateral aspect and sole of the foot.

Where is the most likely site of the lesion?

- 1- Femoral nerve
- 2- Lumbosacral plexus
- 3- Obturator nerve
- 4- Sciatic nerve
- 5- S1 spinal root

Answer & Comments

Answer: 4- Sciatic nerve

Sciatic nerve palsy is a known complication of a total hip replacement (femoral nerve palsy can occur but is much less common).

It causes global weakness of the ankle due to the involvement of both of its branches: tibial nerve (plantarflexion and inversion) and common peroneal nerve (dorsiflexion and eversion).

The right ankle jerk is absent due to tibial nerve involvement.

[Q: 4047] OnExamination 2012 - Neurology

A 39-year-old painter presents with a burning pain in both feet, which has deteriorated over the last six months.

He drinks 60 units of alcohol weekly and has a family history of pernicious anaemia.

On examination he has impairment of all modalities of sensation in both feet but particularly pain, temperature and absent ankle jerks.

What is the most likely diagnosis?

- 1- Alcoholic peripheral neuropathy
- 2- Chronic inflammatory demyelinating polyradiculopathy
- 3- Hereditary sensory neuropathy
- 4- Lead neuropathy
- 5- Vitamin B₁₂ deficiency

Answer & Comments

Answer: 1- Alcoholic peripheral neuropathy

Alcohol abuse and diabetes are the commonest causes of peripheral neuropathy in the United Kingdom.

Vitamin B₁₂ deficiency causes neuropathy that affects only the dorsal column (joint position, light touch and vibration).

Lead neuropathy is purely motor affecting mainly the upper limbs.

Chronic inflammatory demyelinating polyradiculopathy causes mainly motor impairment (distal and proximal).

[Q: 4048] OnExamination 2012 - Neurology

A 25-year-old woman presented with a history of confusion and fever that had worsened gradually over the preceding four days.

On examination she was drowsy and had mild neck stiffness. Neurological examination revealed an extensor left plantar response. A CT scan of her brain showed an area of low attenuation in the right temporo-parietal region.

What is the most likely diagnosis?

- 1- Cerebral toxoplasmosis
- 2- Herpes simplex encephalitis
- 3- Listerial meningoenzephalitis
- 4- Pneumococcal meningitis
- 5- Pyogenic brain abscess

Answer & Comments

Answer: 2- Herpes simplex encephalitis

Herpes simplex encephalitis (HSE) often presents subacutely over several days with declining cerebral function. The temporal or temporo-parietal regions are affected earlier and neuro-imaging usually demonstrates this. However, temporal lobe involvement is not pathognomonic of HSE.

Cerebral toxoplasmosis is the result of reactivation of toxoplasmosis in severely immunocompromised individuals.

Listeriosis is associated with the consumption of soft cheese.

Streptococcus pneumoniae causes acute pyogenic meningitis and is often associated with suppurative otitis media or sinusitis.

Brain abscesses are usually readily demonstrable by cranial CT scans.

[Q: 4049] OnExamination 2012 -
Neurology

A 62-year-old man seeks an opinion due to a tremor mostly affecting the right hand but also latterly the left hand which has gradually deteriorated over five years.

Past medical history includes asthma for which he takes inhaled salbutamol, hypertension for which he takes bendroflumethiazide and lisinopril and depression for which he takes amitriptyline.

He smoked 10 cigarettes daily and drank approximately 15 units of alcohol weekly, noting an improvement in his tremor following alcohol.

Examination revealed some mild titubation and a postural tremor in both arms with no worsening during finger-nose testing.

What is the most likely diagnosis?

- 1- Benign essential tremor
- 2- Hyperthyroidism
- 3- Parkinson's disease
- 4- Physiological tremor
- 5- Salbutamol-induced tremor

Answer & Comments

Answer: 1- Benign essential tremor

The features of relief with alcohol, postural tremor and a slight and rather benign deterioration over five years suggests a diagnosis of benign essential tremor.

Physiological tremor usually affects the hands only.

In this case there is titubation, again a feature of essential tremor.

The mild features argue against Parkinson's disease.

The condition is typically slowly progressive and occurs from approximately 50 years.

[Q: 4050] OnExamination 2012 -
Neurology

A 62-year-old man seeks an opinion about a tremor which mostly affects his right hand but also latterly his left hand and which has gradually deteriorated over five years.

His medical history includes asthma for which he takes inhaled salbutamol, hypertension for which he takes bendroflumethiazide and lisinopril and depression for which he takes amitriptyline.

He smokes 10 cigarettes daily and drinks approximately 15 units of alcohol weekly, noting an improvement in his tremor following alcohol.

Examination reveals some mild titubation and a postural tremor in both arms with no worsening during finger-nose testing.

What is the most likely diagnosis?

- 1- Benign essential tremor
- 2- Hyperthyroidism
- 3- Parkinson's disease
- 4- Physiological tremor
- 5- Salbutamol-induced tremor

Answer & Comments

Answer: 1- Benign essential tremor

The features of relief with alcohol, postural tremor and a slight and rather benign deterioration over five years suggests a diagnosis of benign essential tremor.

Physiological tremor usually affects the hands only.

In this case there is titubation, again a feature of essential tremor.

The mild features argue against Parkinson's disease.

The condition is typically slowly progressive and occurs from approximately 50 years.

[Q: 4051] OnExamination 2012 -
Neurology

A 60-year-old woman presented with a small right pupil, right ptosis and impaired sweating over the ipsilateral forehead. Sweating on the rest of the face was unaffected.

Where is the most likely site of this lesion?

- 1- Cervical spinal cord
- 2- Common carotid artery
- 3- Hypothalamus
- 4- Internal carotid artery
- 5- Lateral medulla

Answer & Comments

Answer: 4- Internal carotid artery

Because the sympathetic plexus accompanying the internal carotid artery innervates sweat glands only to the medial forehead, facial anhydrosis does not occur significantly with postganglionic Horner syndrome.

[Q: 4052] OnExamination 2012 -
Neurology

A 24-year-old man presents with a headache that has been present for nine months. He has headache almost every day, mainly frontal, sometimes with nausea.

Current medication includes paracetamol, brufen and codeine with only transient relief of symptoms. He has a history of depression. Examination was normal.

What is the most likely diagnosis?

- 1- Analgesic misuse headache
- 2- Cluster headache
- 3- Frontal brain tumour
- 4- Headache due to depression
- 5- Migraine

Answer & Comments

Answer: 1- Analgesic misuse headache

This is one of the commonest causes of chronic daily headache (the commonest is chronic tension type headache).

It is commonly caused by the chronic use of analgesics such as codeine phosphate and paracetamol.

Treatment consists of reducing the amount of analgesics gradually until stopped.

[Q: 4053] OnExamination 2012 -
Neurology

Which of the following relate to dopa-decarboxylase inhibitors?

- 1- Enhance the effect of levodopa on the substantia nigra
- 2- Reduce the extracerebral complications of L-dopa therapy
- 3- Have anticholinergic activity
- 4- Should not be given in combination with dopamine agonists
- 5- Prevent L-dopa associated dyskinesias

Answer & Comments

Answer: 2- Reduce the extracerebral complications of L-dopa therapy

A. Dopa-decarboxylase inhibitors prevent the systemic metabolism of levodopa which leads to higher central nervous system (CNS) levels. The effect itself is not enhanced, only the concentration of available levodopa.

B. These include nausea, vomiting, postural hypotension and cardiac arrhythmias.

D. The combination makes dyskinetic movements more likely.

E. No. Dyskinesias are a CNS effect of levodopa.

[Q: 4054] OnExamination 2012 -
Neurology

Which of the following would be the result of a spinal lesion at the level of C8?

- 1- A reduced brachioradialis reflex
- 2- Inability to abduct the shoulder
- 3- Loss of sensation over the lateral aspect of the arm
- 4- Winging of the scapula
- 5- Weakness of finger flexion

Answer & Comments

Answer: 5- Weakness of finger flexion

A. Brachioradialis is the "supinator" reflex and it is mediated by C5/6.

B. Deltoid is supplied by C5/6.

C. Medial; forearm and hand are affected. Lateral aspect of arm is C5.

D. This is caused by paralysis of the long thoracic nerve to serratus anterior (C5, 6, 7).

[Q: 4055] OnExamination 2012 -
Neurology

Which of the following would be expected following distal occlusion of the posterior cerebral artery?

- 1- Cerebellar ataxia
- 2- Contralateral hemiplegia
- 3- Dysarthria
- 4- Homonymous hemianopia
- 5- Palatal palsy

Answer & Comments

Answer: 4- Homonymous hemianopia

The following would also be expected:

Distal (peripheral territory) posterior cerebral artery stroke

Homonymous hemianopia (often upper quadrantic)

Cortical blindness

Verbal dyslexia without agraphia

Hemivisual neglect

Visual hallucinations.

(Harrisons).

[Q: 4056] OnExamination 2012 -
Neurology

A 50-year-old male epileptic presents with paraesthesia of hands and feet. He also has unsteadiness when walking.

On examination he has Dupuytren's contracture in his left hand, a peripheral sensory neuropathy and palpable lymph nodes in his neck and axillae.

Which of the following drugs is the most likely cause of these features?

- 1- Carbamazepine
- 2- Clonazepam
- 3- Lamotrigine
- 4- Phenytoin
- 5- Sodium valproate

Answer & Comments

Answer: 4- Phenytoin

Phenytoin is well known to cause neurological side effects such as peripheral sensory neuropathy and cerebellar ataxia.

Other side effects include:

Gingival hypertrophy

Lymphadenopathy

Hypocalcaemia

Hirsutism.

[Q: 4057] OnExamination 2012 -
Neurology

Which of the following is true of the anticonvulsant, levetiracetam?

- 1- Acts via the gamma-aminobutyric acid (GABA) receptor
- 2- Is associated with increased plasma concentrations of sodium valproate
- 3- Is associated with induction of hepatic cytochrome p450 enzymes
- 4- Is used as monotherapy for the treatment of generalised convulsions
- 5- Is well absorbed via the oral route

Answer & Comments

Answer: 5- Is well absorbed via the oral route

Levetiracetam (Keppra) is an adjunctive treatment for partial seizures with or without secondary generalisation. Its mechanism of action is unknown.

It is rapidly absorbed orally, it does not effect hepatic enzymes but dose reduction is required in renal failure.

The drug appears to be well tolerated with few side effects.

[Q: 4058] OnExamination 2012 -
Neurology

A 72-year-old female presents with general slowness.

Examination reveals a tremor of the hands.

What frequency of tremor would you suspect in Parkinson's disease?

- 1- 1 Hz
- 2- 2 Hz
- 3- 5 Hz
- 4- 8 Hz
- 5- 10 Hz

Answer & Comments

Answer: 3- 5 Hz

The typical tremor associated with Parkinson's disease is 4-6 Hz although in a minority the tremor may be faster - 8 Hz. This rate is more typical of essential tremor.

[Q: 4059] OnExamination 2012 -
Neurology

A 56-year-old woman presents with problematical tremor which has deteriorated over the last three months and she notes that it is exacerbated by changes in position.

She has a past history of asthma for which she is taking inhaled salbutamol and one year ago she underwent liver transplantation for primary biliary cirrhosis for which she takes cyclosporin.

On examination she seems quite well but has a noticeable coarse tremor of her outstretched hands. There are no other abnormalities noticeable on neurological examination.

How should this patient be managed?

- 1- Add benzhexol
- 2- L-dopa
- 3- Propranolol
- 4- Reduce dose cyclosporin
- 5- Reduce dose salbutamol

Answer & Comments

Answer: 4- Reduce dose cyclosporin

Cyclosporin is well known to cause coarse tremor. In the first instance the dose should be reduced. Usually the neurological side effects of cyclosporin are dose dependent.

The tremor with salbutamol tends not to be coarse as described in this case, being approximately 10-12 Hz..

[Q: 4060] OnExamination 2012 - Neurology

Which of the following is true concerning baclofen?

- 1- Acts directly on skeletal muscle
- 2- Causes hallucinations when withdrawn
- 3- Causes rhabdomyolysis
- 4- Reduces Ca²⁺ release from sarcoplasmic reticulum
- 5- Reduces cerebral but not spinal spasticity

Answer & Comments

Answer: 2- Causes hallucinations when withdrawn

The primary site of action is the spinal cord by depressing monosynaptic and polysynaptic transmission. It can hyperpolarise cells by increasing K⁺ conductance and inhibit Ca²⁺ channels in others.

Rhabdomyolysis is caused by:

Clofibrate

Aminocaproic acid

HMG-CoA reductase inhibitors

Neuroleptics (neuroleptic malignant syndrome).

Avoid abrupt withdrawal as it can cause serious side-effects including autonomic dysreflexia.

[Q: 4061] OnExamination 2012 - Neurology

TAR DNA-binding protein 43 (TDP-43) is associated with which neurological dysfunction?

- 1- Demyelinating disease
- 2- Myopathic disease
- 3- Neurodegenerative disease
- 4- Neuro-oncologic disease

5- Peripheral neuropathies

Answer & Comments

Answer: 3- Neurodegenerative disease

TDP43 is a protein that has recently been found to be involved in a multitude of neurodegenerative diseases including dementia and motor neuron disease.

[Q: 4062] OnExamination 2012 - Neurology

A 40-year-old man presents to the Emergency department.

His wife says he has not been himself for the past few days, becoming aggressive over trivial things and yesterday he could not work out how to use the TV remote control. When she confronted him he told her that he had a headache. Today she found him in the kitchen picking at his clothes and smacking his lips. He would not respond to her when she called him. This lasted for a few minutes. Afterwards he was confused and unable to remember this episode.

On examination his temperature is 37.9°C and he is becoming increasingly drowsy. Blood tests show a leucocytosis.

Which of the following is the most likely diagnosis?

- 1- Bacterial meningitis
- 2- HSV encephalitis
- 3- Listerial rhombencephalitis
- 4- Drug overdose
- 5- Subdural haemorrhage

Answer & Comments

Answer: 2- HSV encephalitis

This question emphasises the importance of a collateral history in drowsy patients - the diagnosis is in the patient's wife's description of recent events.

Patients with encephalitis usually complain of a headache.

Encephalitis causes impairment of consciousness. This often progresses from personality change early on leading to confusion and drowsiness.

HSV typically affects the temporal lobes. This can cause complex partial seizures.

HSV infections may cause pyrexia and leucocytosis or leucopenia.

A. Bacterial meningitis is not the answer. The history of personality change and a complex partial seizure is not typical for this condition.

B. The answer is HSV encephalitis. Patients with encephalitis typically complain of headache and have impairment of consciousness. The patient's wife gives a good history of this - he has a change in personality then becomes confused. This progresses to drowsiness on admission. The episode in the kitchen fits with a complex partial seizure. HSV typically affects the temporal lobes and may cause this. The temperature and leucocytosis also fit with an infective cause. This question emphasises the importance of a collateral history in drowsy patients - the diagnosis is in the patient's wife's description of recent events.

C. The answer is not listerial rhombencephalitis. As discussed the history is good for an infective encephalitis. However Listeria tends to affect immunocompromised patients. It tends to cause a basal meningoencephalitis with associated symptoms of lower cranial nerve palsies and myoclonus. This does not fit well.

D. Drug overdose is not the answer. An overdose of antidepressants can cause serotonin syndrome. This is associated with drowsiness, pyrexia and seizures. However the confusion the previous day does not fit. You would also expect the seizures to be generalised.

E. Subdural haemorrhage is not the answer. There is no history of trauma and the pyrexia and leucocytosis do not fit. Subdural haemorrhages are more common in the elderly and alcoholics.

[Q: 4063] OnExamination 2012 - Neurology

A 40-year-old man is admitted with a one day history of increasing drowsiness.

He had a diarrhoeal illness two weeks ago from which he made a full recovery. His wife says that over the past three days he had developed double vision and had begun to 'walk like he was drunk'.

On examination he has mild proximal weakness and brisk symmetrical reflexes. Sensation is intact and plantars are down going.

Which of the following is the most likely diagnosis?

- 1- Bickerstaff's encephalitis
- 2- Miller-Fisher variant Guillain-Barre syndrome
- 3- Multiple sclerosis
- 4- Wallenberg's syndrome
- 5- Weber's syndrome

Answer & Comments

Answer: 1- Bickerstaff's encephalitis

Bickerstaff's encephalitis is usually preceded by an infection, typically Campylobacter jejuni.

It is associated with autoantibodies against gangliosides, typically anti-GQ1b IgG, in the serum.

Bickerstaff's encephalitis affects the brainstem, this may be seen on MRI with hyperintensities on T2 weighted images.

It causes drowsiness, ophthalmoparesis, ataxia and brisk reflexes.

The drowsiness and brisk reflexes can be used to differentiate it from Miller-Fisher.

Bickerstaff's encephalitis is the answer. This is a rare immune disorder affecting the brainstem. It is usually preceded by an infection, typically *Campylobacter jejuni*.

It is associated with autoantibodies against gangliosides, typically anti-GQ1b IgG, in the serum. It causes drowsiness, ophthalmoparesis, ataxia and brisk reflexes. The drowsiness and brisk reflexes can be used to differentiate it from Miller-Fisher.

It may be seen on MRI as hyperintensities in the brain stem on T2 weighted images.

Miller-Fisher variant Guillain-Barre syndrome is not the answer as it is not associated with drowsiness and typically causes reduced or absent reflexes.

Multiple sclerosis (MS) is not the answer. The history is very acute for MS and there is no association with diarrhoea. MS is not typically associated with drowsiness.

Wallenberg's syndrome is not the answer. This is most commonly caused by infarction of the lateral medulla. It causes ipsilateral Horner's syndrome, loss of facial pin-prick and temperature sensation, with preserved light touch and corneal reflex. There is contralateral loss of pain and temperature sense in the limbs and trunk.

Weber's syndrome is not the answer. This is a lesion of the cerebral peduncle and causes an ipsilateral third nerve lesion and contralateral hemiparesis.

[Q: 4064] OnExamination 2012 - Neurology

A 72-year-old man is brought to the Emergency department by his wife. He became agitated and confused whilst out shopping. He is really very upset and complains that he has no recollection about what has happened that day and has no idea

at all how he suddenly got to the supermarket with his wife.

He has a history of hypertension for which he takes ramipril, and he takes aspirin 75 mg on the advice of his doctor, but has no other significant past medical history.

On examination his BP is well controlled at 135/75 mmHg, his pulse is 70 and regular. Neurological examination is normal and he behaves appropriately when asked to perform set tasks.

Investigations show:

Haemoglobin 13.5 g/dl (13.5-17.7)

White cell count $7.0 \times 10^9/L$ (4-11)

Platelets $190 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 108 $\mu\text{mol/l}$ (79-118)

CT head Normal

Which of the following is the most appropriate therapy for him?

1- Clopidogrel

2- Dipyridamole SR and aspirin in combination

3- Fluoxetine

4- Reassurance

5- Sodium valproate

Answer & Comments

Answer: 4- Reassurance

This man's history is typical of that for transient global amnesia.

The cause of transient global amnesia is unknown but it may be related to a migrainous phenomenon or transient ischaemia.

It is claimed that the condition may be associated with neuronal loss in the hippocampal area or abnormal metabolism

by neurones in this area leading to build up of lactate, but definitive proof does not exist.

No specific therapy for the condition is required; specifically no increased use of anti-platelet agents is needed.

[Q: 4065] OnExamination 2012 - Neurology

A 67-year-old man presents with a severe headache, the worst he has ever had, affecting the back of his head and his neck.

On admission to the Emergency department he is very agitated and requires opiate based pain relief for his headache. He has a history of hypertension for which he takes ramipril, amlodipine and indapamide. His BP is elevated at 185/100 mmHg and he has a tachycardia of 90 BPM.

He is severely photophobic and finds it impossible to comply with ophthalmoscopy. Neurological examination, as far as you can tell, is normal.

Investigations show

Haemoglobin 11.1 g/dl(13.5-17.7)

White cell count $4.2 \times 10^9/L$ (4-11)

Platelets $231 \times 10^9/L$ (150-400)

Sodium 143 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

CT head Left parietal lobe haemorrhage

What neurological finding would you most expect?

1- Acalculia

2- Dysphagia

3- Expressive dysphasia

4- Left hemiplegia

5- Contralateral homonymous superior quadrantanopia

Answer & Comments

Answer: 1- Acalculia

The dominant parietal lobe (usually the left) is important for perception, interpretation of sensory information and the formation of motor responses. The non-dominant lobe has a number of visual-spatial functions. Involvement of the optic tract, in either lobe, causes a contralateral homonymous inferior quadrantanopia. Typical signs associated with different lesions are:

Post-central gyrus (anterior parietal lobe), dominant or non-dominant:

- Impaired proprioception
- Impaired two point discrimination
- Agraphism
- Astereognosis
- Sensory +/- visual inattention

Superior parietal lobule, dominant or non-dominant:

- Balint syndrome: optic ataxia
- Impaired spatial processing

Inferior parietal lobule, dominant or non-dominant:

- Sensory extinction
- Asteroagnosia
- Dysgraphaesthesia

Dominant inferior parietal lobule:

- Acalculia
- Agraphia
- Left/right confusion
- Finger agnosia
- Receptive dysphasia
- Alexia or dyslexia
- Gerstmann's syndrome

Non-dominant inferior parietal lobule:

- Geographical agnosia
- Phonagnosia
- Constructional apraxia
- Anosognosia
- Spatial neglect of the contralateral limb
- Dressing apraxia

Expressive dysphasia is caused by damage to the posterior inferior frontal gyrus.

Homonymous superior quadrantanopia is caused by a lesion of the temporal lobe.

Dysphagia is caused by a number of neurological conditions, but not specifically a lesion of the parietal lobe.

[Q: 4066] OnExamination 2012 - Neurology

A 28-year-old woman who is getting married soon comes to the clinic complaining that her right pupil is much larger than the other. She says that she first noticed this a few weeks ago after suffering from an attack of shingles.

On examination the pupil is larger than the other, reacts poorly to light, but appears to have a normal near reflex.

Which of the following is the most likely diagnosis?

- 1- Argyll-Robertson pupil
- 2- Holmes-Adie pupil
- 3- Horner's syndrome
- 4- Normal variant
- 5- Third nerve palsy

Answer & Comments

Answer: 2- Holmes-Adie pupil

The Holmes-Adie pupil usually occurs after a herpes zoster infection, which initially leads

to an abnormally large pupil poorly reactive to light with a normal near reflex.

Over years it gradually diminishes in size actually to be smaller than the non-affected pupil.

The diagnosis is supported by an abnormally vigorous reaction to weak pupil constricting eye drops, which can be compared to the changes seen on the normal side.

[Q: 4067] OnExamination 2012 - Neurology

A 49-year-old owner of a pub is admitted in a confused and agitated state. He has recently tried to stop drinking and according to his wife it is 24 hours since his last drink.

When you see him his BP is elevated at 155/90 mmHg, pulse at 90, and he looks agitated. There are signs of chronic liver disease on physical examination. He is trying to pull the sheets over his head as he tells you he can see a large dog in the next bed.

Investigations show:

Haemoglobin 10.9 g/dl(13.5-18)

White cell count $8.2 \times 10^9/L$ (4-10)

Platelets $190 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (60-120)

Glucose 4.5 mmol/l (3.6-5.8)

ALT 190 IU/l (5-60)

Which of the following is the most likely diagnosis?

- 1- Alcoholic hallucinosis
- 2- Delirium tremens
- 3- Hypomania
- 4- Schizophrenia
- 5- Wernicke's encephalopathy

Answer & Comments

Answer: 1- Alcoholic hallucinosis

As many as 25% of habitual alcohol drinkers may suffer from alcoholic hallucinosis when they withdraw from alcohol for 24 hours or longer. Hallucinations are usually visual or tactile, but may be auditory and persecutory.

Delirium tremens is associated with a much more profound disorientation and agitation, with severe autonomic dysfunction and cardiovascular collapse. It may well be preceded by alcohol withdrawal seizures.

Management of this patient involves B vitamin replacement with a preparation such as Pabrinex, and the use of appropriate withdrawal medication.

[Q: 4068] OnExamination 2012 - Neurology

A 46-year-old man is found to have nystagmus.

On closer examination it is downbeat nystagmus.

Which of the following conditions is the most likely to cause this clinical finding?

- 1- Aqueduct stenosis
- 2- Central cerebellar lesion
- 3- Chiari type I malformation
- 4- Unilateral medial longitudinal fasciculus lesion
- 5- Wernicke's encephalopathy

Answer & Comments

Answer: 3- Chiari type I malformation

Nystagmus is defined as involuntary oscillations of the eyes.

This may be pendular when the oscillations are equal in rate and amplitude, or jerking when there are quick and slow phases. (The quicker phase is used to define the direction.)

Nystagmus may be caused by:

Visual disturbances

Lesions of the labyrinth

The central vestibular connections

Brain stem or cerebellar lesions.

Pendular nystagmus is usually due to loss of macular vision, but may be seen in diffuse brain stem lesions.

Jerking nystagmus which is of constant direction regardless of the direction of gaze, suggests a labyrinthine or cerebellar lesion.

Nystagmus which changes with the direction of gaze suggests widespread central involvement of vestibular nuclei.

Jerking nystagmus present only on lateral gaze, and the fast component of which is in the direction of gaze, indicates a lesion of the brain stem or cerebellum.

Nystagmus confined to one eye suggests a peripheral lesion of the nerve or muscle, or a lesion of the medial longitudinal bundle.

Nystagmus restricted to the abducting eye on lateral gaze (ataxic nystagmus) is due to a lesion of the medial longitudinal bundle between the pons and mid-brain as in multiple sclerosis (MS).

Nystagmus occurring on upward gaze with the fast component upwards (upbeat nystagmus) may be due to a lesion in the mid-brain at the level of the superior colliculus.

Downbeat nystagmus (fast phase downwards) suggests a lesion in the lower part of the medulla. It is therefore typical of the Arnold-Chiari malformation.

Wernicke's or thiamine deficiency is a rare cause of downbeat nystagmus and therefore is not as likely a diagnosis as the Arnold Chiari malformation in the option list.

[Q: 4069] OnExamination 2012 -
Neurology

A 72-year-old man presents with Parkinson's disease.

Which of the following is a likely mechanism underlying the neurodegeneration seen in this condition?

- 1- Aberrant fusion of 2 genes
- 2- Impaired protein degradation
- 3- Over expression of cellular oncogene
- 4- Post-translational modification
- 5- Telomere shortening

Answer & Comments

Answer: 2- Impaired protein degradation

Mutations in either the parkin gene or UCHL1 lead to impaired protein degradation.

The other genetic abnormalities concern other diseases not Parkinson's.

Impaired protein degradation is also seen in other neurodegenerative conditions.

[Q: 4070] OnExamination 2012 -
Neurology

A 67-year-old man has drunk 8 units of alcohol a day for most of his adult life.

He has worsening symptoms of poor memory, a wide-based gait and urinary incontinence for ten months.

What is the most likely diagnosis?

- 1- HIV encephalitis
- 2- Meningovascular syphilis
- 3- Normal pressure hydrocephalus
- 4- Syringomyelia
- 5- Wernicke-Korsakoff syndrome

Answer & Comments

Answer: 3- Normal pressure hydrocephalus

The triad of memory loss, gait difficulties and urinary incontinence will lead towards the diagnosis of normal pressure hydrocephalus.

In this scenario, the alcohol is a distractor.

[Q: 4071] OnExamination 2012 -
Neurology

A 35-year-old man with a known history of epilepsy presents with a skin rash, lymphadenopathy and gingival hypertrophy.

Which of the following medications is most likely to be responsible for his symptoms?

- 1- Carbamazepine
- 2- Lamotrigene
- 3- Lorazepam
- 4- Phenytoin
- 5- Sodium valproate

Answer & Comments

Answer: 4- Phenytoin

Common side effects of phenytoin include gingival hyperplasia, coarsening of the facies, and hirsutism.

Phenytoin is linked to a hypersensitivity syndrome manifested by fever, rash, and lymphadenopathy.

Patients receiving phenytoin may develop pseudolymphoma or, rarely, malignant lymphoma and mycosis-fungoides-like lesions.

[Q: 4072] OnExamination 2012 -
Neurology

A 19-year-old girl presents with recurrent episodes of loss of consciousness.

Over the last two years she has had blackouts which last approximately 30 seconds.. They typically occur when she is standing. These have occurred more frequently over the last week. The last episode was witnessed by her

boyfriend who noted that she collapsed without any abnormal movements. On coming round she was rather drowsy initially but generally fine and recovered relatively quickly.

What is the most likely diagnosis?

- 1- Addison's disease
- 2- Atonic seizures
- 3- Cardiac syncope
- 4- Complex partial seizures
- 5- Vasovagal syncope

Answer & Comments

Answer: 5- Vasovagal syncope

This young girl has features suggestive of vasovagal syncope.

The story suggests that:

The episodes always occur when she is standing (whereas cardiac syncope could occur at any time but may be precipitated by exercise)

That there are no abnormal movements (making epilepsy less likely) and

That there is a pretty full recovery (again making epilepsy less likely).

[Q: 4073] OnExamination 2012 - Neurology

A 30-year-old male presents with a week history of right arm weakness. Originally the problem began with severe pain in the neck which radiated into the right shoulder, which was followed by weakness.

Examination revealed winging of the right scapula with weakness of right shoulder abduction and elbow extension. There was some sensory loss over the lateral aspect of the right shoulder and right triceps reflex was absent.

What is the most likely diagnosis?

- 1- C7 entrapment radiculopathy
- 2- Central C5/6 disc prolapse
- 3- Neuralgic amyotrophy
- 4- Suprascapular nerve entrapment
- 5- Traction of lateral cord of brachial plexus

Answer & Comments

Answer: 3- Neuralgic amyotrophy

Neuralgic amyotrophy is a brachial plexopathy (usually upper brachial plexus) usually preceded by an infective picture.

It usually presents with severe pain for days to weeks followed by weakness and sensory loss over the corresponding territory of the brachial plexus (more commonly C5-7).

It is a self-limiting condition but recovery may be slow (years).

[Q: 4074] OnExamination 2012 - Neurology

A 55-year-old woman with multiple sclerosis is treated for severe hip adductor muscle spasticity and two days later develops double vision.

Which one of the following treatments is she likely to have been given?

- 1- Botulinum toxin
- 2- Dantrolene
- 3- Intrathecal baclofen
- 4- Oral baclofen
- 5- Tizanidine

Answer & Comments

Answer: 1- Botulinum toxin

Botulinum toxin is the treatment of choice for focal dystonia (such as torticollis, and hemi-facial spasm) and focal dystonia.

The primary action of the toxin is to block acetylcholine release at the neuromuscular junction and so to produce muscle weakness.

Occasionally systemic absorption of the toxin can affect distal muscles causing symptoms such as diplopia and dysphagia.

[Q: 4075] OnExamination 2012 - Neurology

A 70-year-old man is admitted with an acute stroke.

Examination revealed a left Horner's syndrome, loss of corneal reflex on the left together with loss of pinprick sensation on the left face.

His left gag reflex was also decreased. He had left limb ataxia with right hemi-sensory loss of pain and temperature sensation.

Which one of the following arterial territories has been affected?

- 1- Basilar
- 2- Left posterior communicating
- 3- Left posterior inferior cerebellar
- 4- Right posterior inferior cerebellar
- 5- Right superior cerebellar

Answer & Comments

Answer: 3- Left posterior inferior cerebellar

The clinical features are typical of lateral medullary syndrome.

They consist of:

Ipsilateral signs of Horner's syndrome

Facial loss

Pharyngeal weakness and ataxia and

Contralateral signs of spinothalamic sensory loss of the limbs.

The posterior inferior cerebellar artery is affected.

[Q: 4076] OnExamination 2012 - Neurology

A 50-year-old man presents with a 12 month history of deteriorating memory. He has otherwise been well and takes no medication.

Which one of the following is most typical of frontal lobe dysfunction?

- 1- Inability to draw a clock face
- 2- Inability to generate a list rapidly
- 3- Inability to perform serial 7s
- 4- Sensory inattention
- 5- Visual field defects

Answer & Comments

Answer: 2- Inability to generate a list rapidly

Frontal lobe dementia is a common neurodegenerative condition. It usually affects patients of 45-65 years old.

A failure to generate a list rapidly is a test of frontal lobe (for example, name animals in 60 seconds or words beginning with the letter F, etc).

Dyscalculia is a manifestation of the dominant parietal lobe.

Sensory inattention is a manifestation of parietal lobe dysfunction.

Visual field defect is a manifestation of:

Occipital lobe (homonymous hemianopia)

Temporal lobe (superior quadrantanopia)

Parietal lobe (inferior quadrantanopia)

pathology.

[Q: 4077] OnExamination 2012 - Neurology

A 30-year-old woman complains of daily frontal headaches for the preceding year. They occur at various times of the day and are worse with stress.

On examination, the left pupil is 2 mm larger than the right. It is reactive to accommodation but not to light.

Which of the following features would be inconsistent with the diagnosis?

- 1- Absent biceps jerk
- 2- Exaggerated response to dilute pilocarpine drops instilled in the left eye
- 3- Fine hand tremor
- 4- Ptosis
- 5- Resolution of anisocoria with time

Answer & Comments

Answer: 4- Ptosis

This patient has an Adie pupil which happens to coexist with tension headache.

An absent biceps jerk would be consistent with Holmes-Adie syndrome.

The characteristic abnormality in this condition is degeneration of parasympathetic nerves in the ciliary ganglion which leads to denervation of the pupil and hence hypersensitivity to dilute pilocarpine drops. The affected pupil is usually larger than the other but may constrict with time.

The cause of the associated areflexia is unknown.

A fine hand tremor may accompany anxiety states associated with tension headache but ptosis requires an organic explanation.

[Q: 4078] OnExamination 2012 - Neurology

A 50-year-old man presented with paraesthesia in the ring and little fingers of his right hand.

On examination there was wasting of the hypothenar eminence of his right hand.

Which one of the following movements would you expect to be weak in this patient?

- 1- Abduction of the thumb
- 2- Adduction of the thumb
- 3- Extension of the little finger
- 4- Flexion of the index finger
- 5- Opposition of the thumb

Answer & Comments

Answer: 2- Adduction of the thumb

The clinical features suggest an ulnar neuropathy. The ulnar nerve supplies the hypothenar muscles (opponens digiti minimi, abductor digiti minimi, flexor digiti minimi), the third and fourth lumbricals, dorsal and palmar interossei and adductor pollicis. It also provides sensory innervation to the fifth digit and medial half of the fourth digit.

Abduction and opposition of the thumb and flexion of the index finger are via the median nerve.

Extension of the little finger is via the radial nerve.

[Q: 4079] OnExamination 2012 - Neurology

A 70-year-old woman has a history of dyspnoea and palpitations for six months.

An ECG at that time showed atrial fibrillation. She was given digoxin, diuretics and aspirin.

She now presents with two short-lived episodes of altered sensation in the left face, left arm and leg. There is poor co-ordination of the left hand. ECHO was normal as was a CT head scan.

What is the most appropriate next step in management?

- 1- Anticoagulation
- 2- Carotid endarterectomy
- 3- Clopidogrel
- 4- Corticosteroid treatment
- 5- No action

Answer & Comments

Answer: 1- Anticoagulation

This patient is having symptoms of transient ischaemic attacks most likely due to a cardiac source of emboli.

A normal echocardiogram (ECHO) or computerised tomography (CT) scan head does not rule out thromboembolic events.

There is an increased risk of strokes in patients with atrial fibrillation and hence with the given symptoms formal anticoagulation with warfarin should be considered.

[Q: 4080] OnExamination 2012 - Neurology

A 92-year-old man was admitted in a confused state. He has a history of immobility due to severe lower back pain. He had been losing weight for three months and had complaints of weakness, urinary frequency, thirst, poor urinary stream and constipation.

Lumbar spine x rays show severe osteopenia and collapse of the body of the vertebra at L3.

Investigations show:

Haemoglobin 9.6 g/dl(13.0-18.0)

Sodium 144 mmol/l (137-144)

Potassium 3.9 mmol/l (3.5-4.9)

Urea 10.4 mmol/l (2.5-7.5)

Creatinine 120 mol/l (60-110)

Glucose 8 mmol/l (3.0-6.0)

Dipstick urine Blood ++, protein +

What is the most important immediate investigation?

- 1- Chest x ray
- 2- Monosodium urate (MSU)
- 3- Prostate specific antigen
- 4- Serum calcium
- 5- Serum protein electrophoresis

Answer & Comments

Answer: 4- Serum calcium

The likely underlying diagnosis is myeloma. The symptoms of constipation, weakness and thirst indicate hypercalcaemia.

Serum calcium should be the immediate investigation.

[Q: 4081] OnExamination 2012 - Neurology

A 23-year-old man presents with visual loss in his right eye and this is diagnosed as optic neuritis.

Which one of the following statements would be seen in an afferent pupillary defect?

- 1- Accommodation response is unaffected
- 2- Hypersensitive response to pilocarpine in the affected eye
- 3- Irregular pupil of the affected eye
- 4- Pupil of affected eye larger than the unaffected eye
- 5- Pupil of affected eye smaller than the unaffected eye

Answer & Comments

Answer: 1- Accommodation response is unaffected

Optic neuropathy does not cause any abnormalities of the shape or size of the pupil.

However the light reaction is diminished.

Accommodation is normal.

[Q: 4082] OnExamination 2012 - Neurology

Which of the following statements about the spinal cord is true?

- 1- A lesion of the left side of the spinal cord at C5 causes pyramidal weakness of the right leg
- 2- Centrally placed spinal cord lesions affect joint position sense before other modalities of sensation
- 3- Conus medullaris lesions cause lower motor neurone signs with absent reflexes
- 4- The spinal cord ends at the lower border of the L3 vertebra
- 5- The spinothalamic tracts are supplied principally by the anterior spinal artery

Answer & Comments

Answer: 5- The spinothalamic tracts are supplied principally by the anterior spinal artery

At the pyramidal decussation (lower medulla), 85% fibres cross over forming the lateral corticospinal tract, the remaining forming the ventral corticospinal tract, the fibres of which eventually cross the cord. Hence, a lesion at left side of C5 will cause weakness of the left leg.

Central spinal cord lesions destroy:

Contiguous structures like the anterior horn cells (lower motor neurone signs)

Decussating sensory fibres (pain and temperature) and

The lateral corticospinal tracts (upper motor neurone signs).

Conus medullaris lesion causes:

Wasting and weakness of leg muscles with fasciculations (lower motor neurone signs) and

Hyper-reflexia especially distally (upper motor neurone signs) supplied by the lower sacral segments (glutei)

with sensory loss of buttocks and perineum.

The spinal cord terminates at lower border of L1 vertebra.

Anterior spinal arteries supply corticospinal and spinothalamic tracts, and anterior horns of the grey matter.

[Q: 4083] OnExamination 2012 - Neurology

Which of the following is true of myasthenia gravis (MG)?

- 1- Electrical recordings of single motor unit activity commonly reveal variation in the latency of the various muscle fibre responses (jitter)
- 2- Neurotransmitter released at the motor end plate is greatly reduced
- 3- Repetitive stimulation of a motor nerve produces a reduction in the amplitude of the fifth response compared with the first in 98% of cases (electrodecremental test)
- 4- Subjective improvement in muscle strength following edrophonium is diagnostic of the condition
- 5- There is a strong association with anti-noradrenergic receptor antibodies

Answer & Comments

Answer: 1- Electrical recordings of single motor unit activity commonly reveal variation in the latency of the various muscle fibre responses (jitter)

This is a difficult question.

Anti-acetylcholine (ACh) receptor antibodies are typically found in myasthenia gravis (MG) resulting in reduced ACh receptor numbers but sufficient neurotransmitter is released. This leads to fatiguable weakness.

Single fibre electromyography (EMG) is the most sensitive test for myasthenia gravis. It simultaneously records the variability in potentials of two muscle fibres innervated by an individual axon: jitter. Although abnormal jitter is not specific for MG and may occur in polymyositis and ALS, a large degree of jitter

with minimal other abnormalities is suggestive of the diagnosis. Jitter is the most sensitive emg index in MG but is not specific of the condition. The nerve conductions and electromyogram (EMG) studies are usually normal in myasthenia gravis, but the repetitive stimulation of a nerve may demonstrate decrements of the muscle action potential (far less than 98%). An increase in decrement on stimulation at 3Hz is detectable in some patients.

The Tensilon (edrophonium) challenge test can be used to diagnose MG, or distinguish it from cholinergic crisis. Edrophonium given at increasing doses should produce improvement in muscle strength within a minute. It does this by blocking the breakdown of acetylcholine by cholinesterase and temporarily increases the level of acetylcholine at the neuromuscular junction. However, a positive response is not specific and may occur in amyotrophic lateral sclerosis. There is a risk of bradycardia, asystole and heart block and atropine should therefore be available. Airway support should be used as respiratory weakness can be exacerbated after the edrophonium wears off. Although improved muscle strength after edrophonium is seen, it is not diagnostic but depends more on the clinical presentation and presence of AChR ab.

[Q: 4084] OnExamination 2012 - Neurology

A 40-year-old male is diagnosed with dystrophia myotonica.

Which one of the following features would be expected in this patient?

- 1- Autosomal recessive inheritance
- 2- Cataracts
- 3- Fasciculations would predominate
- 4- Preserved tendon reflexes despite muscle wasting
- 5- Progressive external ophthalmoplegia

Answer & Comments

Answer: 2- Cataracts

Dystrophia myotonica is an autosomal dominant condition with variable penetrance.

Symptoms characteristically begin from the age of 20-30 with weakness and myotonia.

Cataracts

Ptosis

Frontal baldness

Gynaecomastia

Diabetes and

Reduced reflexes with myotonia

are features.

[Q: 4085] OnExamination 2012 - Neurology

A 72-year-old male presents with diplopia.

Which one of the following features would suggest a third nerve palsy?

- 1- Enophthalmos
- 2- Constricted pupil
- 3- Convergent strabismus
- 4- Increased lacrimation
- 5- Unreactive pupil to light

Answer & Comments

Answer: 5- Unreactive pupil to light

Enophthalmos is seen in Horner's syndrome.

In a third nerve palsy there would be a dilated not constricted pupil and a divergent squint, with the affected eye deviated 'down and out'.

[Q: 4086] OnExamination 2012 - Neurology

Which of the following investigations best

supports a diagnosis of new variant CJD?

- 1- CSF analysis
- 2- CT brain
- 3- EMG
- 4- MRI brain
- 5- VEPs

Answer & Comments

Answer: 4- MRI brain

MRI brain typically shows bilateral posterior thalamic high signal abnormalities in a patient with new variant Creutzfeldt-Jakob disease (CJD).

Cerebrospinal fluid (CSF) analysis only shows non-specific changes.

EMG and CT brain are normal.

Sporadic CJD (and not new variant CJD) is associated with specific EEG changes.

[Q: 4087] OnExamination 2012 - Neurology

A 25-year-old woman was recently diagnosed with rheumatoid arthritis.

She has developed weakness, double vision and tiredness.

Examination reveals bilateral weakness of eye abduction, bilateral ptosis, slightly reduced proximal motor power in the limbs, normal reflexes and sensation.

What is the diagnosis?

- 1- Chronic progressive external ophthalmoplegia.
- 2- Guillain-Barre syndrome.
- 3- Multiple sclerosis.
- 4- Myasthenia gravis.
- 5- Polymyositis

Answer & Comments

Answer: 4- Myasthenia gravis.

Myasthenia gravis is well known to be associated with other autoimmune diseases such as pernicious anaemia, thyroid disease and rheumatoid arthritis.

In Guillain-Barre syndrome you would expect absent reflexes.

Polymyositis does not usually cause ptosis or ophthalmoplegia.

[Q: 4088] OnExamination 2012 - Neurology

A 75-year-old man presents with 12 months history of cognitive impairment, parkinsonism, intermittent confusion and generalised myoclonus.

He was started on 62.5 three times daily of Sinemet. In the following two months he has started experiencing visual hallucinations.

Which of the following is the most likely diagnosis?

- 1- Alzheimer's disease
- 2- Diffuse Lewy body disease
- 3- Idiopathic Parkinson's disease
- 4- Multiple system atrophy
- 5- Progressive supranuclear palsy

Answer & Comments

Answer: 2- Diffuse Lewy body disease

Diffuse Lewy body disease presents with:

Cognitive impairment

Visual hallucinations

Intermittent confusion

Parkinsonism

Myoclonus and

Marked sensitivity to neuroleptic treatment.

Visual hallucinations in Parkinson's disease treated with L-dopa usually appear late (more than two years after initiation of treatment).

Visual hallucinations are not features of multiple system atrophy or progressive supranuclear palsy.

[Q: 4089] OnExamination 2012 - Neurology

A 65-year-old man presents with four months history of swallowing difficulties (worse with liquids than solids).

He also complains of nasal regurgitation, coughing and choking episodes during meals and slight dysarthria. He lost one stone over the last eight weeks.

Which of the following investigations is the most appropriate for this case?

- 1- Acetyl choline receptors antibodies
- 2- Barium swallow
- 3- CXR
- 4- Gastroscopy
- 5- Tumour markers

Answer & Comments

Answer: 1- Acetyl choline receptors antibodies

Nasal regurgitation, coughing and choking episodes during meals, dysphagia that is worse with liquids than solids and dysarthria indicate neurogenic dysphagia.

Important causes at this age include myasthenia gravis and motor neuron disease. Lambert Eaton syndrome very rarely affects the bulbar muscles.

Myasthenia gravis is an antibody-mediated disorder which reduces the efficiency of signal transduction across the neuromuscular junction. There is resultant weakness of the innervated muscle, which increases with fatigue. The commonest associated auto-

antibodies are against the nicotinic acetylcholine receptor (AChR). The majority of patients are affected by ptosis, ophthalmoplegia, dysarthria and dysphasia. Treatment is with cholinesterase inhibitors, and immunosuppression in severe cases.

Mechanical dysphagia (for example, oesophageal and gastric carcinoma, oesophageal stricture, etc) causes dysphagia that is worse with solids than liquids. Nasal regurgitation and dysarthria are not usually accompanying features of mechanical dysphagia.

No abnormality would be expected on chest x-ray, barium swallow or gastroscopy with myasthenia gravis, and tumour markers are not raised.

A number of you suggest achalasia could be the diagnosis in this case. However, achalasia typically affects solids more than liquids, or solids and liquids equally (rather than the opposite as in this case). It typically presents earlier than this (25-40y age). Chest pain is a predominant feature, and this level of weight loss is unusual.

[Q: 4090] OnExamination 2012 - Neurology

An 18-year-old female presents with a three day history of progressive weakness and numbness of her legs, urinary retention and back pain for two weeks following an upper respiratory infection.

On examination there is spastic paraparesis, sensory level up to T5, extensor plantars.

Examination of cranial nerves and upper limbs is normal. MRI of the spine is normal.

Of the following, which is the most likely diagnosis?

- 1- Anterior spinal artery occlusion
- 2- Guillain-Barre syndrome
- 3- Multiple sclerosis

- 4- Post-infectious transverse myelitis
5- Thoracic disc prolapse

Answer & Comments

Answer: 4- Post-infectious transverse myelitis

Transverse myelitis describes a heterogeneous group of conditions that are characterised by acute or subacute motor, sensory and autonomic spinal cord dysfunction. The clinical signs are caused by an interruption in ascending and descending pathways in the transverse plane of the spinal cord. A sensory level is characteristic. Midline or dermatomal neuropathic pain can be present. Urinary incontinence or retention, bowel incontinence or constipation, and sexual dysfunction are common but vary in severity. These signs develop over hours to days, and are usually bilateral.

There are a variety of causes, but it most often occurs as an autoimmune phenomenon after an infection or vaccination, or as a result of direct infection, an underlying systemic autoimmune disease, or an acquired demyelinating disease. For a significant proportion of cases no cause is found.

MRI is indicated to rule out the presence of structural lesions, and determine the presence of myelitis which enhances with gadolinium in the acute phase. There may be more than one area of myelitis, and the lesions usually span at least two vertebral segments. In the acute phase the MRI may be normal.

Treatment in the acute phase aims to halt the progression and initiate resolution of the inflammatory cord lesion. Corticosteroids are first line, and are initially given in high doses intravenously. Plasma exchange can be given to those who fail to respond. Patients with demyelinating disease can be started on long-term immunosuppression.

The prognosis is highly variable, and improvement can take three months and longer to develop. A rapidly progressive course, severe weakness, hypotonia and areflexia are predictors of poor prognosis. 50-70% of patients have partial or complete recovery.

Whilst multiple sclerosis may be a possible underlying cause in this young lady, the proximity to an infection and the lack of history of other neurological deficits makes it less likely.

Guillain-Barre syndrome presents with ascending progressive symmetrical weakness, with lower motor neurone signs.

Anterior spinal artery occlusion typically presents with a flaccid paraplegia or quadriplegia (depending on the level). It is usually associated with atherosclerosis or aortic dissection, and would therefore be unusual in this age group.

A thoracic disc prolapse would be seen on MRI.

[Q: 4091] OnExamination 2012 - Neurology

Which of the following is caused by a lesion of the frontal lobe?

- 1- Apraxia
- 2- Broca's (expressive) aphasia
- 3- Cortical blindness
- 4- Homonymous hemianopia
- 5- Visuospatial neglect

Answer & Comments

Answer: 2- Broca's (expressive) aphasia

Lesions of the frontal lobe include:

Difficulties with task sequencing and executive skills

Expressive aphasia (receptive aphasias and temporal lobe lesion)

Primitive reflexes

Perseveration (repeatedly asking the same question or performing the same task)

Anosmia

Changes in personality.

Lesions of the parietal lobe include:

Apraxias

Neglect

Astereognosis (unable to recognise an object by feeling it)

Visual field defects (typically homonymous inferior quadrantanopia).

They may also cause acalculia (inability to perform mental arithmetic).

Lesions of the temporal lobe cause:

Visual field defects (typically homonymous superior quadrantanopia)

Wernicke's (receptive) aphasia

Auditory agnosia

Memory impairment.

Occipital lobe lesions include:

Cortical blindness (blindness due to damage to the visual cortex and may present as Anton syndrome where there is blindness but the patient is unaware or denies blindness)

Homonymous hemianopia

Visual agnosia (seeing but not perceiving objects - it is different to neglect since in agnosia the objects are seen and followed but cannot be named).

[Q: 4092] OnExamination 2012 - Neurology

Which of the following may cause a downbeat

nystagmus?

1- Aqueduct stenosis

2- Benign paroxysmal vertigo

3- Central cerebellar lesion

4- Chiari type I malformation

5- Unilateral medial longitudinal fasciculus lesion

Answer & Comments

Answer: 4- Chiari type I malformation

Nystagmus is defined as involuntary oscillations of the eyes.

This may be pendular when the oscillations are equal in rate and amplitude, or jerking when there are quick and slow phases. (The quicker phase is used to define the direction.)

Nystagmus may be caused by:

Visual disturbances

Lesions of the labyrinth

The central vestibular connections

Brain stem or cerebellar lesions.

Pendular nystagmus is usually due to loss of macular vision, but may be seen in diffuse brain stem lesions.

Jerking nystagmus which is of constant direction regardless of the direction of gaze, suggests a labyrinthine or cerebellar lesion.

Nystagmus which changes with the direction of gaze suggests widespread central involvement of vestibular nuclei.

Jerking nystagmus presents only on lateral gaze, the fast component of which is in the direction of gaze and indicates a lesion of the brain stem or cerebellum.

Nystagmus confined to one eye suggests a peripheral lesion of the nerve or muscle, or a lesion of the medial longitudinal bundle.

Nystagmus restricted to the abducting eye on lateral gaze (ataxic nystagmus) is due to a lesion of the medial longitudinal bundle between the pons and mid-brain as in multiple sclerosis (MS).

Nystagmus occurring on upward gaze with the fast component upwards (upbeat nystagmus) may be due to a lesion in the mid-brain at the level of the superior colliculus.

Downbeat nystagmus (fast phase downwards) suggests a lesion in the lower part of the medulla. It is therefore typical of the Arnold-Chiari malformation.

Wernicke's encephalopathy is another rare cause.

[Q: 4093] OnExamination 2012 - Neurology

Which of the following associations of muscles and nerve supply are not true?

- 1- Deltoid and C5
- 2- Gastrocnemius and S1
- 3- Long flexors of fingers and C6
- 4- Quadriceps and L3
- 5- Triceps and C7

Answer & Comments

Answer: 3- Long flexors of fingers and C6

Finger flexors and extensors are supplied by C8.

[Q: 4094] OnExamination 2012 - Neurology

A 43-year-old gentleman has been brought to the Emergency department by his partner.

He was diagnosed with HIV infection 10 years ago and his CD4 count has been maintained on triple therapy.

He has recently been dismissed from work for poor performance. He has lost interest in

cooking and socialising over the past 10 months. There has been a slurring in his speech. His partner feels he has been more aggressive and withdrawn, however in the past few days he has started to have hallucinations.

What is the likely diagnosis?

- 1- Cryptococcal meningitis
- 2- HIV dementia
- 3- Progressive multifocal leukoencephalopathy
- 4- Schizophrenia
- 5- Toxoplasmosis

Answer & Comments

Answer: 2- HIV dementia

HIV infection can cause dementia that progresses over a longer time period than progressive multifocal leukoencephalopathy (PML). Symptoms are of:

Confusion

Depression

Reduced concentration

Behavioural changes

Psychosis

Speech and balance problems, as well as

Muscle weakness.

Patients with cryptococcal meningitis present with headache, fever, vomiting and few neurological signs.

PML can present at any CD4 count with ataxia, behavioural changes and focal neurological signs, often progressing over a period of months to paresis or even coma.

Toxoplasmosis presents with headache, fever and seizures. It has a typical CT head scan with ring enhancing lesions.

This patient's symptoms may be compatible with schizophrenia, however given his HIV status and neurology HIV dementia is more likely.

[Q: 4095] OnExamination 2012 - Neurology

A 58-year-old man presents with central back pain which shoots down to his left foot. There is paraesthesia over the lateral aspect of the left foot, impaired ankle jerk and weakness of plantarflexion. His right leg is normal.

What is the most likely cause of his pain?

- 1- Cervical disc prolapse
- 2- Cauda equina syndrome
- 3- L3/4 disc prolapse
- 4- L4/5 disc prolapse
- 5- L5/S1 disc prolapse

Answer & Comments

Answer: 5- L5/S1 disc prolapse

The L5/S1 disc can compress the S1 nerve root causing

Sciatic pain

Loss of plantarflexion

Impaired S1 reflex (ankle jerk) and

Paraesthesia over the lateral aspect of the foot.

Regarding the options:

A is incorrect as signs would be bilateral and involve paraplegia.

B is incorrect as there would be bilateral signs and bladder involvement.

C and D are incorrect as they involve the wrong spinal root.

E is correct as it is the S1 nerve root that is involved.

[Q: 4096] OnExamination 2012 - Neurology

A 45-year-old woman presents to the GP with loss of sensation over the lateral three and a half fingers of her right hand, tenderness over her right forearm and inability to make a tight fist.

She complains of pain in her right arm when twisting door handles anticlockwise. Phalen's and Tinel's tests are negative. She is otherwise neurologically intact.

What is the most likely diagnosis?

- 1- Carpal tunnel syndrome
- 2- Diabetic polyneuropathy
- 3- Multiple sclerosis
- 4- Pronator teres syndrome
- 5- Stroke

Answer & Comments

Answer: 4- Pronator teres syndrome

Entrapment of the median nerve by pronator teres causes a median nerve neuropathy, which is worse during pronation of the forearm.

Examination involves excluding carpal tunnel syndrome and pronation of the affected forearm against resistance, which brings on the pain. Unlike carpal tunnel syndrome, the median nerve proximal to the wrist may be tender to palpation.

Regarding the options:

A is incorrect as Tinel's and Phalen's tests are negative.

B is incorrect as diabetic neuropathies tend to be bilateral and affect the feet before the hands.

C is incorrect as there is a peripheral nerve lesion.

D is the correct answer as the median nerve is affected, and the pain is exacerbated by pronation.

E is incorrect as there is a peripheral not central nerve lesion.

[Q: 4097] OnExamination 2012 - Neurology

An old man presents to his GP with difficulty driving. He reports not seeing cars approaching from the right.

On examination he has a right inferior homonymous quadrantanopia.

What is the most likely diagnosis?

- 1- Right occipital lobe
- 2- Left parietal lobe
- 3- Right temporal lobe
- 4- Left optic tract
- 5- Optic chiasm

Answer & Comments

Answer: 2- Left parietal lobe

Lesions affecting the optic radiation cause a contralateral homonymous quadrantanopia.

The upper part of the visual field flows through the temporal lobe, whilst the inferior part flows through the parietal lobe. This can be remembered with the mnemonic, PITS - parietal inferior, temporal superior.

Lesions of the optic tract (before the lateral geniculate body) result in a contralateral homonymous hemianopia, whilst lesions of the optic chiasm cause a bitemporal hemianopia.

Regarding the options:

A is incorrect because it is ipsilateral and would cause a hemianopia.

B is correct as it is the contralateral optic radiation that causes homonymous quadrantanopia.

C is incorrect because it is ipsilateral and would cause a superior quadrantanopia.

D is incorrect because optic tract lesions cause hemianopsia.

E is incorrect because optic chiasm lesions cause bitemporal hemianopsia.

[Q: 4098] OnExamination 2012 - Neurology

A 64-year-old man presents to the hospital with bleeding. He has a heavy dependence on alcohol.

On examination he has petechiae and bleeding gums.

What is the likely vitamin deficiency?

- 1- B1
- 2- B12
- 3- C
- 4- E
- 5- K

Answer & Comments

Answer: 3- C

Alcoholics have malabsorption resulting in multiple possible vitamin deficiencies.

Deficiencies in:

B1 or thiamine can result in Wernicke's encephalopathy

Vitamin B₁₂ or cyanocobalamin can result in subacute degeneration of the spinal cord

Vitamin K can result in anticoagulant effects and elevated INR causing more profuse bleeding

Vitamin E deficiency can result in myopathies, neuropathies and red cell dyscrasias.

[Q: 4099] OnExamination 2012 -
Neurology

Which area supplied by the median nerve will be spared if the problem is at the carpal tunnel?

- 1- Hypothenar eminence
- 2- Lateral three digits
- 3- Medial two digits
- 4- Thenar eminence
- 5- Volar surface of the hand

Answer & Comments

Answer: 4- Thenar eminence

The hypothenar eminence is supplied by the ulnar nerve as are the volar surface and the medial two digits (the fourth and fifth digits, remember the dermatomal map has palms facing outwards).

The lateral three digits are supplied by the median nerve but are affected by carpal tunnel syndrome.

[Q: 4100] OnExamination 2012 -
Neurology

What is the likelihood of being seizure-free after a second or third antiepileptic in patients previously untreated for epilepsy?

- 1- 8%
- 2- 14%
- 3- 20%
- 4- 35%
- 5- 47%

Answer & Comments

Answer: 2- 14%

A study of patients with previously untreated epilepsy demonstrated that 47% achieved control of seizures with the use of their first single drug.

Fourteen per cent became seizure-free during treatment with a second or third drug.

An additional 3% became seizure-free with the use of two drugs simultaneously.

Birbeck GL, Hays RD, Cui X, Vickrey BG. (2002).

'Seizure reduction and quality of life improvements in people with epilepsy'.
Epilepsia 43 (5): 535-538

[Q: 4101] OnExamination 2012 -
Neurology

What is the mechanism of action of fingolimod?

- 1- Inhibits IL-2 transcription
- 2- Ceramide synthase inhibitor
- 3- Interferon agonist
- 4- Monoclonal antibody to anti-alpha 4 integrin
- 5- Shifts Th1 cell to Th2 cell populations

Answer & Comments

Answer: 2- Ceramide synthase inhibitor

Fingolimod is a new agent for multiple sclerosis. Its primary mode of action is its activity at the sphingosine-1-phosphate receptor 1, but it has also been reported to be a cannabinoid receptor antagonist as well as a ceramide synthase inhibitor. It is an immunomodulator, which sequesters lymphocytes in lymph nodes. It has been shown to reduce the rate of relapses in relapsing-remitting MS by over half.

IFN beta-1 is used in multiple sclerosis.

Glatiramer acts to shift the T cell population from a pro-inflammatory to a regulatory state, and is also used in MS.

Cyclosporin inhibits IL-2 transcription, and is an immunomodulator used in a number of conditions (including transplants).

Natalizumab is a monoclonal antibody to alpha-4 integrin. It can be used in the treatment of multiple sclerosis.

[Q: 4102] OnExamination 2012 - Neurology

You are asked to review a 32-year-old woman on the labour ward.

She has just given birth to a healthy female child and was recovering on the ward when the midwives noticed a deterioration in her conscious level and a grand mal seizure which was self-terminating after about five minutes.

A few minutes before the seizure they said that she had increasing problems with nausea, vomiting and a severe frontal headache. Apparently there was a short period of hypotension associated with the delivery.

On examination she is drowsy with a GCS of 12, her BP is 145/91 mmHg. She has bilateral papilloedema and appears to have bilateral third nerve palsies.

Investigations show

Haemoglobin 11.1 g/dl(11.5-16.5)

White cell count $5.2 \times 10^9/L$ (4-11)

Platelets $180 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 88 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely diagnosis?

- 1- Cerebral venous thrombosis
- 2- Embolic stroke
- 3- Idiopathic epilepsy
- 4- Migraine
- 5- Subarachnoid haemorrhage

Answer & Comments

Answer: 1- Cerebral venous thrombosis

This woman's symptoms, the onset of which has occurred a few hours after the birth of her child, are suggestive of cerebral venous thrombosis.

A number of conditions predispose to the condition, including

Pregnancy and use of the oral contraceptive pill

Inherited coagulation disorders

Collagen vascular disease.

Signs and symptoms may vary from headache, nausea and vomiting, to a progressive reduction in conscious level and eventual coma.

Magnetic resonance venography is extremely valuable in confirming the diagnosis.

Anti-coagulation is the treatment of choice.

[Q: 4103] OnExamination 2012 - Neurology

In herpes simplex encephalitis which of the following statements is correct?

- 1- Brain magnetic resonance imaging (MRI) is characteristically normal
- 2- Cold sores or genital herpes are usually present
- 3- Fits are uncommon
- 4- Temporal lobe involvement is common
- 5- Viral identification by polymerase chain reaction (PCR) on cerebrospinal fluid (CSF) is non-specific

Answer & Comments

Answer: 4- Temporal lobe involvement is common

MRI brain normally shows changes in the temporal lobes.

Presenting features include fever, headache, vomiting, reduced consciousness and seizures.

There may be dysphasia, hallucinations and peculiar behaviour.

There are usually no skin manifestations of herpes simplex infections.

The virus is rarely isolated from CSF but may be detected by PCR.

[Q: 4104] OnExamination 2012 - Neurology

A 17-year-old female presents with three headaches over a six month period.

She describes the headaches as severe, right-sided and lasting for twelve hours and associated with nausea and photophobia. Each is preceded by spots before her eyes.

What is the most appropriate initial treatment for this patient?

- 1- Diclofenac at the onset of the next attack
- 2- Ergotamine suppository at the onset of the next attack
- 3- Paracetamol plus metoclopramide at the onset of the next attack
- 4- Prophylaxis with propranolol
- 5- Sumatriptan at the onset of the next attack

Answer & Comments

Answer: 3- Paracetamol plus metoclopramide at the onset of the next attack

First line treatment of acute migraine consists of simple analgesic (either soluble paracetamol or aspirin) and an antiemetic (usually domperidone or metoclopramide).

Second line treatment includes the use of non-steroidal anti-inflammatory drugs such as diclofenac.

If the above measures fail to alleviate the attacks, then triptan therapy (for example, sumatriptan) is indicated.

It is important for patients to take the treatment as early as possible.

Long term prophylaxis with drugs (for example, propranolol) is indicated only if the attacks are frequent (more than two a month).

[Q: 4105] OnExamination 2012 - Neurology

A 40-year-old woman presents with fatigue.

She has a six month history of secondary amenorrhoea and galactorrhoea.

Examination shows an obese lady with a BMI of 36 kg/m². Neurological examination is normal.

A prolactin is measured at 3124 mU/L (normal <550mU/L) and thyroid function tests reveal a Free T₄ of 7.5 nmol/l and a TSH of 120 mU/l. A CT scan shows a bulky pituitary gland.

Which of the following is the likely diagnosis?

- 1- Cushing's syndrome
- 2- Hypothyroidism
- 3- Macroprolactinoma
- 4- Microprolactinoma
- 5- Type 2 diabetes

Answer & Comments

Answer: 2- Hypothyroidism

Hypothyroidism is not an uncommon cause of hyperprolactinaemia and should be part of the work up of all patients with an elevated prolactin.

The clinical scenario here would be consistent with a diagnosis of hypothyroidism.

Macroprolactin may masquerade as hyperprolactinaemia and most laboratories

now carry out this assay if requested in patients with hyperprolactinaemia. Cabergoline or bromocriptine should only be commenced if a macroprolactinoma is confirmed.

A bulky pituitary gland on CT scan is not a significant finding and an MRI of the pituitary is required to delineate the anatomy of the pituitary gland.

Bitemporal hemianopia would be a feature of a macroprolactinoma impinging on the optic chiasm.

[Q: 4106] OnExamination 2012 - Neurology

A 21-year-old man is admitted with severe acute onset headache.

He is disoriented and drowsy and has neck stiffness. Investigations suggest a diagnosis of subarachnoid haemorrhage (SAH).

What grade of SAH does this patient have based on the Hunt & Hess classification?

- 1- Grade three
- 2- Grade one
- 3- Grade two
- 4- Grade four
- 5- Grade five

Answer & Comments

Answer: 1- Grade three

This gentleman's history is suggestive of subarachnoid haemorrhage (SAH). The Hunt and Hess scale grades SAH thus:

1. Asymptomatic or minimal headache, plus slight neck stiffness.
2. Moderate or severe headache with neck stiffness, but no neurological deficit other than cranial nerve palsy.
3. Drowsiness with confusion or mild focal neurology.

4. Stupor with moderate to severe hemiparesis or mild decerebrate rigidity.

5. Deeply comatose with severe decerebrate rigidity.

Severity and mortality increase with grade.

[Q: 4107] OnExamination 2012 - Neurology

A 65-year-old man presents with unsteadiness, rigidity of movement and tremor of the right hand.

Which of the following features most strongly suggest idiopathic Parkinson's disease?

- 1- Intention tremor
- 2- Slowness of the movement
- 3- The asymmetry of tremor
- 4- Titubation
- 5- Tremor that disappears when he sleeps

Answer & Comments

Answer: 3- The asymmetry of tremor

Asymmetry and resting tremor are more common in idiopathic Parkinson's disease than other parkinsonian syndromes.

Intention tremor is seen in cerebellar diseases.

[Q: 4108] OnExamination 2012 - Neurology

A 65-year-old male presents with bilateral leg pain.

There is no relevant past medical history, and no excess alcohol use. Both knee reflexes are reduced.

Fasting glucose is 6.5 mmol/L.

Which is the next investigation most likely to confirm the diagnosis?

- 1- B12 and folate
- 2- Chest x ray

- 3- CSF examination
- 4- MRI spine
- 5- Oral glucose tolerance test

Answer & Comments

Answer: 5- Oral glucose tolerance test

The suggestion of bilateral leg pain, weakness and reduced knee reflexes with an impaired fasting glucose concentration suggests a diagnosis of diabetic amyotrophy. This is confirmed with a formal OGTT.

Diabetic amyotrophy is not uncommonly a presenting feature of diabetes in the elderly. The features are of an asymmetrical but bilateral quadriceps wasting and weakness with diminished reflexes.

[Q: 4109] OnExamination 2012 - Neurology

A 30-year-old female was commenced on carbamazepine for partial complex seizures and was also advised to discontinue her moderate alcohol consumption.

Therapeutic concentrations of carbamazepine were achieved within four days with a dose of 200 mg daily but the dose needed to be increased to 400 mg daily within two weeks to achieve a therapeutic plasma concentration.

Which one of the following is likely to account for this observation?

- 1- Auto-induction of carbamazepine metabolism
- 2- Auto-inhibition of carbamazepine metabolism
- 3- Cessation of alcohol intake
- 4- Concomitant prescription of the oral contraceptive pill
- 5- Reduced bioavailability of carbamazepine

Answer & Comments

Answer: 1- Auto-induction of carbamazepine metabolism

Alcohol is a liver enzyme inducer therefore stopping the alcohol should increase the activity of the carbamazepine not reduce its activity.

It is well recognised that carbamazepine is a P450 enzyme inducer but it is less well appreciated that it causes auto-induction and so would require increase in dose to maintain the same therapeutic concentration.

[Q: 4110] OnExamination 2012 - Neurology

A 15-year-old girl presents with a two week history of headaches and double vision. She had also noticed an episode where her vision dimmed after sneezing.

On examination her BMI was 32.4 kg/m², she had bilateral optic disc swelling and a partial left sixth cranial nerve palsy was present.

What is the most likely diagnosis?

- 1- Benign intracranial hypertension
- 2- Graves' ophthalmopathy
- 3- Multiple sclerosis
- 4- Pituitary tumour
- 5- Sagittal vein thrombosis

Answer & Comments

Answer: 1- Benign intracranial hypertension

This patient has the features of benign intracranial hypertension which may be associated with reduction of vision with manoeuvres that raise intracranial pressure and is associated with sixth nerve palsies.

There are no features to suggest Graves' ophthalmopathy nor multiple sclerosis.

A pituitary tumour would be likely to produce visual field constriction which is not mentioned in this history.

A sagittal vein thrombosis is a potential differential diagnosis here but is less likely than BIH.

[Q: 4111] OnExamination 2012 - Neurology

An 18-year-old female presents 12 weeks into an unplanned pregnancy.

She had been diagnosed with epilepsy six years ago which was well controlled on sodium valproate and had been taking the combined oral contraceptive pill for three years.

Which of the following is correct concerning this patient?

- 1- Lamotrigine should be substituted for sodium valproate
- 2- She should be advised to have a termination of her pregnancy.
- 3- Sodium valproate interaction with the oral contraceptive increased the risk of pregnancy.
- 4- The dose of sodium valproate should be increased.
- 5- There is an increased risk of a neural tube defect in her fetus.

Answer & Comments

Answer: 5- There is an increased risk of a neural tube defect in her fetus.

This patient has become pregnant on valproate. This therapy has controlled her seizures and should not be changed now.

However, there is an increased risk of neural tube defects associated with valproate and this could be reduced by folate therapy.

Valproate is not an enzyme inducer and unlike other anticonvulsants would not speed up metabolism of the OCP.

It is entirely up to the individual whether she wishes to pursue the pregnancy or not.

[Q: 4112] OnExamination 2012 - Neurology

A 25-year-old male presents to casualty with weakness of his right hand.

Examination reveals weakness of right wrist and finger extension.

What is the most likely diagnosis?

- 1- Axillary nerve palsy
- 2- C8 nerve root lesion
- 3- Proximal median nerve lesion
- 4- Radial nerve lesion
- 5- Ulnar nerve lesion at the elbow

Answer & Comments

Answer: 4- Radial nerve lesion

Weakness of wrist extension with wrist drop and weakness of finger extension are typical of a radial nerve lesion.

[Q: 4113] OnExamination 2012 - Neurology

A 48-year-old female patient develops an acute, severe and isolated right C6 radiculopathy affecting both the motor and sensory roots.

She is examined in an EMG clinic three weeks after the onset of symptoms.

Which of the following statements is true?

- 1- Absent sensory nerve potentials would be expected on examination of the thumb and index finger on the right.
- 2- A repeat examination 12 months later is likely to reveal rapidly recruited low

amplitude short duration motor units in the clinically involved muscle on EMG.

- 3- Fibrillation potentials would be expected in the right extensor carpi ulnaris and extensor pollicis brevis.
- 4- Triceps tendon jerk is likely to be depressed or absent.
- 5- Voluntary motor unit activity may be absent in the right biceps.

Answer & Comments

Answer:

[Q: 4114] OnExamination 2012 - Neurology

A 48-year-old man presented with a two week history of recurrent severe right-sided peri-orbital headache, frequently nocturnal and occurring at least once daily, usually lasting an hour.

He had noticed lacrimation from the right eye and blockage of the right nostril during the headache.

At the time of the examination he was free from headache and there were no abnormal physical signs.

Which of the following is the most likely diagnosis?

- 1- Cluster headache
- 2- Intracranial aneurysm
- 3- Orbital pseudotumour
- 4- Right maxillary sinusitis
- 5- Trigeminal neuralgia

Answer & Comments

Answer: 1- Cluster headache

Cluster headaches are more common in men (M:F 10:1).

They usually present nocturnally (early morning).

They are paroxysmal (occur in clusters).

They are associated with autonomic symptoms:

Lacrimation

Ptosis

Pupil constriction

Nasal congestion

Redness of eye

Swelling of eyelid.

Examination between the attacks should be normal.

[Q: 4115] OnExamination 2012 - Neurology

A 57-year-old woman is referred to the clinic with progressive hearing loss affecting her left ear and tinnitus.

She had been diagnosed with Meniere's disease some two years earlier and feels that her problems are slowly getting worse with vertigo and double vision recent additional features.

Her GP prescribed some betahistine but it does not seem to be working.

On examination her BP is 134/72 mmHg, pulse is 70 and regular, her BMI is 29.

There is coarse nystagmus when she looks towards the left, nystagmus is rapid when she looks to the right. There is a deficient corneal reflex on the left. Audiometry reveals significant sensorineural hearing loss affecting the left side.

Which of the following is the most appropriate next intervention?

- 1- Added cyclizine
- 2- CT brain
- 3- Increased dose of betahistine
- 4- MRI brain
- 5- Referral for Hallpike manoeuvre

Answer & Comments

Answer: 4- MRI brain

The pattern of nystagmus, slowly progressive symptoms of hearing loss, tinnitus, and loss of corneal reflex fits best with a diagnosis of acoustic neuroma. As such an MRI brain is the investigation of choice.

There is no role for increased medical therapy, betahistine or cyclizine in the management of acoustic neuroma. As such neither of those options is appropriate.

CT is not as sensitive as MRI for detection of acoustic neuroma, whereas MRI can detect tumours as small as 1-2 mm, tumours as large as 1.5 cm have been missed on CT.

The Hallpike manoeuvre is considered in the diagnosis of benign positional vertigo.

[Q: 4116] OnExamination 2012 - Neurology

Which of the following is true regarding cerebral palsy?

- 1- Epilepsy is present in 40%.
- 2- Hearing loss is present in 5%.
- 3- Learning impairment is present in 30%.
- 4- The incidence is 2 per 100 live births.
- 5- Visual impairment occurs in 50%.

Answer & Comments

Answer: 1- Epilepsy is present in 40%.

Cerebral palsy is a disorder of movement and posture due to a non-progressive lesion of the motor pathways in the developing brain.

The clinical manifestations tend to evolve with age. The incidence is 2 per 1000 live births, and other problems are common and reflect more widespread damage to the brain.

These include:

Learning impairment in 60%

Epilepsy in 40%

Squints in 30%

Hearing loss and visual impairment in 20%

Speech and language disorders.

In addition, there may be considerable behavioural problems.

[Q: 4117] OnExamination 2012 - Neurology

The action of noradrenaline (NA) released at sympathetic nerve endings is terminated by which of the following?

- 1- Enzymatic decarboxylation
- 2- Enzymatic inactivation by catechol-O-methyl transferase
- 3- Oxidative deamination by monoamine oxidase
- 4- Removal by the circulating blood
- 5- Re-uptake of noradrenaline by the axonal terminals

Answer & Comments

Answer: 5- Re-uptake of noradrenaline by the axonal terminals

A popular question for the examination but simple physiology gets the right answer here.

The effects of neurotransmitter release are principally terminated by neuronal uptake.

Intraneuronal NA is usually taken back up into the neurosecretory granules and a small amount is metabolised by monoamine oxidase (MAO).

Even smaller quantities that escape into the circulation are metabolised by catechol-O-methyltransferase (COMT).

[Q: 4118] OnExamination 2012 - Neurology

A 15-year-old boy presents with tremor of

both hands.

Over the previous months he has developed a mild dysarthria. He has a history of behavioural problems, of a depressive / psychotic nature.

Which of the following is the most likely diagnosis?

- 1- Alzheimer's disease
- 2- Huntington's disease
- 3- Neuroacanthocytosis
- 4- Variant Creutzfeldt-Jakob disease
- 5- Wilson's disease

Answer & Comments

Answer: 5- Wilson's disease

Wilson's disease is a rare disorder of copper metabolism which is inherited as an autosomal recessive disease.

It is associated with:

Extrapyramidal features (tremor, parkinsonism, dystonia)

Dysarthria

Psychiatric features

Cirrhosis

A deposit of brownish-green pigment around the margin of the cornea (Kayser-Fleischer ring).

Variant Creutzfeldt-Jakob disease is characterised by myoclonus and rapid onset dementia.

[Q: 4119] OnExamination 2012 - Neurology

A 50-year-old old man is admitted to hospital unconscious, and smelling of alcohol.

One hour after admission, he becomes suddenly sweaty with a regular tachycardia of 110 bpm and a BP of 100/50 mmHg.

What is the diagnosis?

- 1- Alcohol withdrawal.
- 2- Hepatic encephalopathy.
- 3- Hypoglycaemia.
- 4- Subdural haematoma.
- 5- Wernicke's encephalopathy.

Answer & Comments

Answer: 3- Hypoglycaemia.

This is a bit early for alcohol withdrawal particularly as the patient is admitted smelling of alcohol.

The most likely diagnosis is hypoglycaemia.

We do not have any clinical findings to suggest any of the other alternatives.

[Q: 4120] OnExamination 2012 - Neurology

A 36-year-old man has a three month history of pain in his feet and lower legs. He was diagnosed as having diabetes at age 14 and treated with insulin. He is a cannabis smoker and drinks 30 units of alcohol per week.

On examination he has impaired pain and temperature sensation in feet and lower legs, normal joint position and vibration sense. His reflexes are normal.

What is the diagnosis?

- 1- Alcoholic polyneuropathy.
- 2- Chronic inflammatory demyelinating polyneuropathy (CIDP)
- 3- Diabetic polyneuropathy.
- 4- Syringomyelia.
- 5- Vitamin B₁₂ deficiency.

Answer & Comments

Answer: 3- Diabetic polyneuropathy.

The history suggests small fibre painful peripheral sensory neuropathy. The

commonest cause is diabetes. Joint position sense and vibration are carried through large fibres, and are therefore affected later. Sensory nerves are affected more than motor so often reflexes remain intact.

Vitamin B₁₂ deficiency causes impairment of joint position and vibration. Chronic inflammatory demyelinating polyneuropathy (CIDP) causes a large fibre peripheral neuropathy with areflexia.

In syringomyelia you have impaired pain and temperature in the upper limbs.

Typically with alcoholic polyneuropathy all fibre types are affected and it is seen with a higher alcohol consumption than 30 units. Pain is usually a more dominant feature. It should definitely feature as part of the differential diagnosis.

[Q: 4121] OnExamination 2012 - Neurology

A 50-year-old woman presented to her GP with a four month history of progressive distal sensory loss and weakness of both legs and arms. The weakness and numbness had extended to the elbows and knees. She had great difficulty in fine manipulation and had become unsteady on her feet. She had osteoarthritis in her neck, but did not take any regular medication. She was a non-smoker and did not drink any alcohol. There was no family history of any neurological disease.

On examination, cranial nerves and fundoscopy were normal. Examination of the upper limb revealed bilaterally reduced tone at the elbows and wrists with absent biceps, triceps and supinator jerks. There was mild weakness of shoulder abduction and adduction 4/5 with marked weakness of handgrip and elbow flexion, extension 3/5.

Sensory examination revealed reduced pinprick sensation extending from the hand to the elbow and vibration was felt at the

elbow. Lower limb examination revealed some mild weakness of hip flexion and extension with marked weakness of dorsiflexion and plantarflexion. Both knee and ankle jerks were absent and both plantar responses were mute. There was absent sensation to all modalities affecting both feet extending to the knees.

A lumbar puncture was performed and yielded the following data:

Opening pressure 14 cm H₂O (5-18)

CSF protein 0.75 g/L (0.15-0.45)

CSF white cell count 10 cells per ml (<5 cells)

CSF white cell differential 90% lymphocytes

CSF red cell count 2 cells per ml (<5 cells)

Nerve conduction studies showed multifocal motor and sensory conduction block with prolonged distal latencies.

What is the likely diagnosis in this patient?

- 1- Cervical spondylosis
- 2- Chronic inflammatory demyelinating neuropathy (CIDP)
- 3- Guillain-Barré syndrome
- 4- Hereditary motor and sensory neuropathy (HMSN)
- 5- Multifocal motor neuropathy

Answer & Comments

Answer: 2- Chronic inflammatory demyelinating neuropathy (CIDP)

The history is compatible with a subacute sensory and motor peripheral neuropathy.

Causes of such conditions include inflammatory neuropathies such as CIDP chronic inflammatory demyelinating polyneuropathy (CIDP) and paraproteinaemic neuropathies.

CIDP is characterised by progressive weakness and impaired sensory function in the upper and lower limbs. The cause of the

demyelination is not understood, but it is more common in young adults and in men. It presents with abnormal sensation (which typically begins distally), weakness of the limbs, areflexia and fatigue.

Treatment for CIDP includes corticosteroids, plasmapheresis and intravenous immunoglobulin. Physiotherapy is an effective adjunct. The course varies widely, and patients may be left with residual neurology or suffer a number of relapses.

Guillain-Barre syndrome (GBS) is an acute post-infectious neuropathy, thought possibly to be a post-infectious phenomenon, which reaches its peak in severity within six weeks. CIDP is closely linked to GBS, and is thought by some to be its chronic counterpart. Both CIDP and GBS can affect motor and sensory nerves, and it is the four month history which distinguishes the two here.

Cervical spondylosis would cause upper motor neurone signs such as hyperreflexia, extensor plantar response and possibly a sensory level.

HMSN is normally a very chronic neuropathy developing over many years and usually with a family history of the condition.

Multifocal motor neuropathy is a treatable neuropathy affecting motor conduction only. It is associated with antibodies to a ganglioside component of peripheral myelin.

[Q: 4122] OnExamination 2012 - Neurology

A 19-year-old girl presents at the antenatal clinic.

She is approximately six weeks pregnant and the pregnancy was unplanned. She has a two year history of grand mal epilepsy for which she takes carbamazepine. She has had no fits for approximately six months. She wants to continue with her pregnancy if it is safe to do so.

She is worried about the anticonvulsant therapy and its effects on the baby. She asks how she should be managed.

Which of the following management plans is the most appropriate in this case?

- 1- Advise termination due to drug teratogenicity
- 2- Continue with carbamazepine
- 3- Stop carbamazepine until the second trimester
- 4- Switch therapy to phenytoin
- 5- Switch therapy to sodium valproate

Answer & Comments

Answer: 2- Continue with carbamazepine

The patient and fetus are at far more risk from uncontrolled seizures than from any potential teratogenic effect of the therapy.

In pregnancy total plasma concentrations of anticonvulsants fall, so the dose may need to be increased.

The potential teratogenic effects (particularly neural tube defects) of carbamazepine do need to be explained and in an effort to reduce this risk she should receive folate supplements.

Screening with alpha fetoprotein (AFP) and second trimester ultrasound are required. Vitamin K should be given to the mother prior to delivery.

There is no point in switching therapies as this could precipitate seizures in an otherwise stable patient.

Similarly both phenytoin and valproate are associated with teratogenic effects. (

[Q: 4123] OnExamination 2012 - Neurology

A 19-year-old girl presents at the antenatal clinic.

She is approximately six weeks pregnant and the pregnancy was unplanned. She has a two year history of grand mal epilepsy for which she takes carbamazepine. She has had no fits for approximately six months. She wants to continue with her pregnancy if it is safe to do so.

She is worried about the anticonvulsant therapy and its effects on the baby. She asks how she should be managed.

Which of the following management plans is the most appropriate in this case?

- 1- Advise termination due to drug teratogenicity
- 2- Continue with carbamazepine
- 3- Stop carbamazepine until the second trimester
- 4- Switch therapy to phenytoin
- 5- Switch therapy to sodium valproate

Answer & Comments

Answer: 2- Continue with carbamazepine

The patient and fetus are at far more risk from uncontrolled seizures than from any potential teratogenic effect of the therapy.

In pregnancy total plasma concentrations of anticonvulsants fall, so the dose may need to be increased.

The potential teratogenic effects (particularly neural tube defects) of carbamazepine do need to be explained and in an effort to reduce this risk she should receive folate supplements.

Screening with alpha fetoprotein (AFP) and second trimester ultrasound are required. Vitamin K should be given to the mother prior to delivery.

There is no point in switching therapies as this could precipitate seizures in an otherwise stable patient.

Similarly both phenytoin and valproate are associated with teratogenic effects. (

[Q: 4124] OnExamination 2012 - Neurology

Frontal lobe brain damage is associated with which of the following?

- 1- Astereognosis
- 2- Auditory agnosia
- 3- Dressing apraxia
- 4- Focal epileptic fits
- 5- Perseveration

Answer & Comments

Answer: 5- Perseveration

Frontal lobe brain damage is classically associated with personality change and deterioration in intellect, but perseveration may also occur.

The lesion for astereognosis and acalculia would be in the parietal lobe and dressing apraxia in the non-dominant parietal lobe.

Focal epileptic fits and auditory agnosia are characteristically associated with temporal lobe damage.

Apraxia may result from lesions in the temporoparietal cortex, dominant frontal cortex and corpus callosum.

[Q: 4125] OnExamination 2012 - Neurology

A 25-year-old female presents with a two day history of diplopia and unsteadiness.

Two weeks ago she suffered an upper respiratory tract infection.

On examination there is complete ophthalmoplegia, areflexia and gait ataxia.

Which of the following blood tests is the most likely to confirm the underlying diagnosis?

- 1- Acetylcholine receptors antibodies

- 2- Anti GM1 antibodies
- 3- Anti GQ1b antibodies
- 4- Anti-Hu antibodies
- 5- Anti-Purkinje cell antibodies

Answer & Comments

Answer: 3- Anti GQ1b antibodies

The most likely diagnosis is Miller Fisher syndrome (variant of Guillain-Barre syndrome). It consists of complete or partial ophthalmoplegia, areflexia and ataxia. It usually follows antecedent infections. Serum IgG antibody to the ganglioside GQ1b is present in more than 95% of patients. It is highly specific for the syndrome.

Elevated levels of antibodies to the glycolipid ganglioside-monosialic acid (GM1 antibodies) have been shown in some instances to be associated with certain neurological disorders:

Lower motor neuron syndromes

Amyotrophic lateral sclerosis

Multiple sclerosis

Other multifocal neuropathies and

Systemic lupus erythematosus (SLE) with central nervous system involvement.

Neuronal nuclear (Hu) antibodies (NNA) are found in a number of paraneoplastic syndromes, including

Subacute sensory neuronopathy

Paraneoplastic encephalomyelitis and

Paraneoplastic cerebellar degeneration

and are associated with small cell lung carcinoma.

Purkinje cell cytoplasmic antibodies are useful for identifying individuals with subacute cerebellar degeneration or peripheral

neuropathy due to a remote (autoimmune) effect of gynecologic or breast carcinoma.

[Q: 4126] OnExamination 2012 - Neurology

A 50-year-old man presented with 18 months history of paraesthesia of his feet and hands.

On examination there is numbness of glove and stocking distribution with generalised hyporeflexia. Nerve conduction studies revealed demyelinating sensory polyneuropathy.

Which of the following conditions is the most likely diagnosis?

- 1- Alcohol abuse
- 2- Chronic inflammatory demyelinating polyneuropathy
- 3- Diabetes
- 4- Vasculitis
- 5- Vitamin B₁₂ deficiency

Answer & Comments

Answer: 2- Chronic inflammatory demyelinating polyneuropathy

Causes of demyelinating polyneuropathy include

Guillain-Barre syndrome

Chronic inflammatory demyelinating polyneuropathy (CIDP)

Paraproteinaemia

Hereditary motor sensory neuropathy

Refsum's disease

HIV infection

Amiodarone.

Causes of axonal polyneuropathy are

Alcohol abuse

Diabetes

Vasculitis

Vitamin deficiencies.

The difference here is between demyelinating and axonal neuropathies.

[Q: 4127] OnExamination 2012 - Neurology

A 68-year-old man presents with progressive visual impairment. On examination there is an incongruous homonymous hemianopia.

What is the most likely anatomical site of the neurological lesion?

- 1- Chiasma
- 2- Occipital lobe
- 3- Optic nerve
- 4- Optic radiation
- 5- Optic tract

Answer & Comments

Answer: 5- Optic tract

Causes of optic neuropathy:

A central scotoma

An optic tract lesion

An incongruous homonymous hemianopia

A chiasmal lesion

A bitemporal hemianopia

An optic radiation and occipital lobe lesion

A congruous homonymous hemianopia.

More on field defects

[Q: 4128] OnExamination 2012 - Neurology

A 35-year-old man has wrist drop of his right hand.

Examination reveals a small area of sensory loss on the dorsum of the hand.

Which of the following nerves is likely to be involved?

- 1- Long thoracic nerve
- 2- Median nerve
- 3- Radial nerve
- 4- T1 nerve root
- 5- Ulnar nerve

Answer & Comments

Answer: 3- Radial nerve

This is a typical radial nerve palsy.

[Q: 4129] OnExamination 2012 - Neurology

A 35-year-old woman was admitted to the Emergency department six months ago with urinary retention. She was catheterised and discharged the same day having recovered function.

She now is suffering with sudden onset blurred vision and pain on looking upwards. She works in an agrochemical laboratory. She takes no medication. There is a family history of breast cancer.

What test is likely to confirm diagnosis?

- 1- Ceruloplasmin level
- 2- CT brain
- 3- Lumbar puncture
- 4- MRI brain
- 5- Organophosphate level

Answer & Comments

Answer: 4- MRI brain

This woman is likely to have multiple sclerosis (MS) given that she has had two neuropathies separated in time and space.

MRI is the gold standard for diagnosing MS, when periventricular white matter plaques of

different ages and in different locations should be seen.

CT brain will not show these changes.

LP should show oligoclonal bands (immunoglobulins within CSF). These can be seen in MS as well as systemic lupus erythematosus (SLE), Lyme disease, neurosarcoidosis, Guillain-Barre syndrome and others.

Ceruloplasmin levels are used to diagnose Wilson's disease.

Organophosphate levels could be used if poison is suspected, but her symptoms would be very different with salivation, bradycardia, bronchospasm and urination, diarrhoea and miosis.

[Q: 4130] OnExamination 2012 - Neurology

A 19-year-old woman presents to the Emergency department with a severe headache, vomiting and right hemiplegia. She has recently begun the progesterone only pill, but has no other past medical history of note.

On examination her blood pressure is 155/80 mmHg, her pulse is 80 and regular and she is in obvious pain. There is a 3/5 power weakness affecting both her right upper and lower limb. Her reflexes are normal.

Investigations show:

Haemoglobin 12.0 g/dl(11.5-16.0)

White cell count $6.1 \times 10^9/L$ (4-11)

Platelets $241 \times 10^9/L$ (150-400)

ESR 9 mm/hr(<10)

Sodium 139 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 82 $\mu\text{mol/l}$ (79-118)

MRI brain normal

Which of the following is the most appropriate treatment for her?

1- Acetazolamide

2- Diclofenac

3- Ergotamine

4- Sumatriptan

5- Zolmitriptan

Answer & Comments

Answer: 2- Diclofenac

Ergot derived compounds and triptans are contraindicated for the treatment of hemiplegic migraine because of the risk of precipitating a stroke.

Whilst acetazolamide has found favour as a treatment for hemiplegic migraine, data are unconvincing.

[Q: 4131] OnExamination 2012 - Neurology

A 54-year-old man being seen in the neurology clinic for a tremor is noted to have a shuffling gait.

Examination reveals difficulty with vertical gaze and an AMTS of 6/10.

What is the most likely diagnosis?

1- Corticobasal degeneration

2- Idiopathic benign essential tremor

3- Parkinson's disease

4- Progressive supranuclear palsy (PSP)

5- Wilson's disease

Answer & Comments

Answer: 4- Progressive supranuclear palsy (PSP)

Progressive supranuclear palsy is characterised by features of parkinsonism, difficulty with vertical gaze due to supranuclear paralysis of upward and downward gaze and cognitive impairment. It is also known as Steele-Richardson-Olszewski

syndrome, is progressive like Parkinson's disease, but does not respond to L-dopa.

Regarding the options:

A is incorrect as it does not cause vertical gaze disturbance.

B is incorrect as there is more than a tremor.

C is incorrect as there is more than parkinsonism.

D is correct as the triad of parkinsonism, vertical gaze palsy and cognitive impairment suggests PSP.

E is incorrect as vertical gaze is affected.

[Q: 4132] OnExamination 2012 - Neurology

A 40-year-old patient is being evaluated in your clinic for headaches.

On examination you notice that the left pupil constricts and then enlarges and constricts again while shining the pen torch on the eye.

What is this finding called?

- 1- Hippus
- 2- Horner's pupil
- 3- Iridocyclitis
- 4- Relative afferent papillary defect
- 5- Tonic pupil

Answer & Comments

Answer: 1- Hippus

Hippus is papillary athetosis. It is typically a benign finding. It is a spasmodic rhythmical dilation and contraction of the pupil. It is particularly noticeable when pupils are tested with a light, but is independent of eye movements or light. Pathological hippus is rare but is recognised with aconite poisoning, trauma, cirrhosis and renal disease (possibly due to frontal lobe dysfunction).

Iridocyclitis is inflammation of the uvea and is a form of anterior uveitis.

A relative afferent papillary defect is detected with the swinging light test, however in this case the pen torch is held on one eye only.

A Horner's pupil is a miotic pupil caused by damage to the sympathetic chain.

A tonic pupil or Holmes-Adie pupil is a dilated pupil caused by parasympathetic damage.

[Q: 4133] OnExamination 2012 - Neurology

A 55-year-old man presents with neck pain.

One week previously he had attended for a sigmoidoscopy and was given intravenous sedation during this procedure. One day prior to admission his neck and shoulders had become stiff.

On examination, the temperature was 38.0°C, blood pressure was 100/60 mmHg and heart rate 100 bpm.

There were absent biceps jerks and weakness of trapezius, deltoid and triceps bilaterally. The cranial nerves and lower limbs were normal.

There was a soft systolic murmur, and the chest was clear.

Which examination is likely to confirm the diagnosis?

- 1- Cervical spine X-ray
- 2- CT head
- 3- Echocardiography
- 4- Lumbar puncture
- 5- MRI neck

Answer & Comments

Answer: 5- MRI neck

The features suggest a paraspinal abscess affecting C4-C6 given the neurological findings.

The investigation of the patient should include all of the above tests.

Paraspinal abscess is often associated with infection in an intravenous (IV) line, which may or may not be apparent as cellulites.

Neurological signs, once apparent, should lead to rapid investigation as once they are present recovery of strength may be slow, or not at all.

A magnetic resonance imaging (MRI) of the neck should delineate the anatomy of the abscess, which will not be seen on a computerised tomography (CT) scan of the head.

However, given that these lesions are usually due to seeding of *Staphylococcus aureus*, endocarditis is a possibility.

Cerebral spinal fluid (CSF) should show an elevated protein with raised white cells, and a low/normal glucose.

[Q: 4134] OnExamination 2012 - Neurology

Which one of the following statements is correct?

- 1- The abducens nerve supplies the lacrimal gland
- 2- The facial nerve supplies the parotid salivary gland
- 3- The oculomotor nerve supplies the dilator pupillae muscle
- 4- The trochlear nerve supplies the superior rectus muscle
- 5- The vagus nerve supplies the palatal muscles

Answer & Comments

Answer: 5- The vagus nerve supplies the palatal muscles

The lacrimal gland is supplied by the facial nerve.

The glossopharyngeal nerve supplies the parotid salivary gland controlling salivary secretions.

The oculomotor nerve carries parasympathetic efferents to the sphincter pupillae muscle.

The optic nerve carries sympathetic postganglionic fibres to the dilator pupillae muscle.

The trochlear nerve supplies the superior oblique muscle.

The oculomotor nerve innervates the superior rectus.

[Q: 4135] OnExamination 2012 - Neurology

A 32-year-old scientist presents to the emergency department with a right facial weakness. He has recently returned from a conference in the USA. There is no history of systemic illness but on examination he has mild neck stiffness and a painful right wrist and knee with a right facial palsy.

Investigations were as follows:

Hb 12 g/dl(13.0-18.0)

WCC $7 \times 10^9/L$ (4-11)

Platelets $190 \times 10^9/L$ (150-400)

Clotting Normal

ESR 32 mm/1st hour(0-15)

Sodium 138 mmol/l (137-144)

Potassium 4.0 mmol/l (3.5-4.9)

Urea 6.9 mmol/l (2.5-7.5)

Creatinine 76 $\mu\text{mol/l}$ (60-110)

Calcium and LFTs Normal

CXR Normal

CT head Normal

CSF: Protein 1.2 g(0.15-0.45)

CSF: WCC 67 (97% lymphocytes)

CSF No organisms seen

What is the most likely diagnosis?

- 1- Behçet's disease
- 2- HIV associated neuropathy
- 3- Lyme disease
- 4- Sarcoidosis
- 5- Tuberculous meningitis

Answer & Comments

Answer: 3- Lyme disease

All the answers are possible causes of a facial palsy.

The high protein and lymphocytosis of the cerebrospinal fluid (CSF) imply an acute or sub-acute infective process. Neurosarcoidosis is thus unlikely.

The main clinical features of Behçet's are not present - orogenital ulceration, iritis and pathergy.

HIV is usually associated with a peripheral sensory neuropathy.

TB meningitis is likely to lead to a generalised systemic illness.

The fact that the patient has recently been to America and has a unilateral facial palsy makes Lyme disease the most likely diagnosis. Lyme disease is spread by the bite of ticks of the genus Ixodes that are infected with Borrelia burgdorferi.

[Q: 4136] OnExamination 2012 - Neurology

Which vertebral level and corresponding structure is correct?

- 1- C4 and bifurcation of the carotid artery
- 2- T2 and manubriosternal joint
- 3- T8 and aortic opening in the diaphragm
- 4- T10 and opening for vena cava in diaphragm

- 5- T12 and oesophageal opening in the diaphragm

Answer & Comments

Answer: 1- C4 and bifurcation of the carotid artery

- A. The carotid artery bifurcates at C4.
- B. The manubriosternal joint (angle of Louis) lies at the level of the T4/5 intervertebral disk.
- C. The aortic opening is at T12.
- D. The caval opening in the diaphragm lies at T8.
- E. The oesophageal opening of the diaphragm lies at T10.

[Q: 4137] OnExamination 2012 - Neurology

An adolescent boy presents with unexplained neurological illness.

Which one of the following would suggest a specific cause of substance abuse?

- 1- A history of attention deficit disorder.
- 2- A history of family conflict.
- 3- A history of low self-esteem.
- 4- A history of social isolation.
- 5- Deposits around the mouth.

Answer & Comments

Answer: 5- Deposits around the mouth.

An increasing number of adolescents are experimenting with alcohol, drugs and solvents, usually soon after entering secondary school. Unfortunately, this includes a rising number of young girls smoking.

Factors associated with drug use include low self-esteem, social isolation, depression, family conflicts and other conduct disorders.

Presentations suggestive of substance abuse include altered behaviour, sniffer's rash, injection sites, chronic upper respiratory tract infection, irregular pulse, glue stains on the skin or clothes, and acute intoxication - ataxia, coma, respiratory depression and cardiac arrhythmia.

The only specific indicators of substance abuse among the options in this case are, therefore, the deposits around the mouth which are most likely to be glue.

Sniffer's rash consists of inflammation and ulceration around the mouth and nose.

[Q: 4138] OnExamination 2012 - Neurology

A 45-year-old female primary school teacher presents with shortness of breath and weakness.

There is a diarrhoeal illness going around her school. She is normally fit and well, and takes no medication.

On examination she has marked weakness in her left and right legs, power 2/5 in ankle and knee extension, increasing to 3/5 in hip extension. There is an absence of knee and ankle reflexes, with up going plantar reflex. Sensation is intact.

Considering the likely diagnosis, what test would you order next?

- 1- Anti-GQ1b antibodies
- 2- Campylobacter jejuni antibody level
- 3- CT brain
- 4- Nerve conduction testing
- 5- Vital capacity

Answer & Comments

Answer: 5- Vital capacity

It is likely that this lady has Guillain-Barre syndrome (GBS), an immune-mediated acute inflammatory demyelinating polyneuropathy.

It often follows infection, especially viral or Campylobacter jejuni. Its most common presentation is with progressive, symmetric, ascending weakness, with hyporeflexia, with or without autonomic and sensory features. In severe cases it can affect respiratory and cardiovascular function.

Therefore, especially given that this lady feels breathless; it is of utmost importance to record her vital capacity, and to monitor it until recovery, as approximately 30% of patients require intubation.

GBS is usually a clinical diagnosis as treatment and ITU admission need to be organised urgently.

Campylobacter jejuni serology may help to find the precipitant of GBS, however only 40% of cases have positive serology, and it will not save this patient's life.

CT brain will be of little help as this patient is demonstrating lower motor neurone signs (flaccid paralysis with hyporeflexia).

Nerve conduction studies will show a slowing/delay in conduction, this will help to confirm your diagnosis, but will not save her life.

Anti-GQ1b antibodies are found in Miller Fisher syndrome, a variant of GBS, with ophthalmoplegia, areflexia and ataxia

[Q: 4139] OnExamination 2012 - Neurology

Causes of dilated pupils include which of the following?

- 1- Argyll Robertson pupil
- 2- Ethylene glycol poisoning
- 3- Myotonic dystrophy
- 4- Organophosphate poisoning
- 5- Pontine haemorrhage

Answer & Comments

Answer: 2- Ethylene glycol poisoning

Causes of dilated pupils include:

Holmes-Adie (myotonic) pupil

Third nerve palsy

Drugs and poisons (atropine, cobalt [CO], ethylene glycol).

Causes of small pupils include:

Horner's syndrome

Old age

Pontine haemorrhage

Argyll Robertson pupil

Drugs and poisons (opiates, organophosphates).

[Q: 4140] OnExamination 2012 - Neurology

A 67-year-old gentleman presents with purulent cough and fever. He has a right lower lobar consolidation on x ray.

This is his third hospital admission for right sided pneumonia. He is not a smoker. His wife reports that he has been choking on food for the past few months and she has noticed that he has been stumbling and dragging his left foot for about five months.

On examination he has atrophy of his quadriceps bilaterally with fasciculations. There is loss of ankle jerk on the left with power 3/5, positive Babinski sign and normal sensation. His right leg has hyperreflexic ankle jerks but absence of knee jerk. There is also marked weakness throughout and fasciculations. Sensation is intact.

What is the likely diagnosis?

1- Amyotrophic lateral sclerosis

2- Charcot-Marie-Tooth disease

3- Huntington's disease

4- Miller Fisher syndrome

5- Multiple sclerosis

Answer & Comments

Answer: 1- Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis (ALS) is a form of motor neurone disease.

It causes degeneration of upper (UMN) and lower motor neurones (LMN), therefore giving a mixed picture with fasciculations and spasticity, weakness and hypo- or hyperreflexia. Sensation and autonomic function are usually unaffected.

Cognition is usually normal, although they may have emotional lability.

Patients usually notice stumbling gait or foot drop if legs affected first, they may progress to more 'bulbar' signs or arm signs.

The diagnosis of ALS requires mixed UMN and LMN signs that are unattributable to any other disease. There is no definitive test for ALS, however MRI, EMG and NCS may help.

Charcot-Marie-Tooth disease is an hereditary sensory and motor neuropathy. There are several types with different genes identified. The features are pes cavus, 'champagne bottle' legs, hyporeflexia and fasciculations with distal sensory loss. Twenty five per cent of patients have a palpable popliteal nerve.

Huntington's disease is a neurodegenerative genetic disorder that is autosomal dominant. The features are of choreiform movements, problems with coordination and walking, behavioural and psychiatric problems. The disease leads eventually to dementia and premature death.

Miller Fisher is a form of Guillain-Barré syndrome (GBS) with areflexia, ataxia and ophthalmoplegia.

Multiple sclerosis would present in this age group and sex. It is due to autoimmune

mediated demyelination. To make the diagnosis there must be two separate attacks separated in time and space (that is, affecting two different nerves and on two separate occasions).

The commonest signs and symptoms are

Optic neuritis

Sensory loss

Spinal cord symptoms with spasticity

Autonomic dysfunction of bladder and bowel

Constitutional symptoms such as fatigue and depression.

[Q: 4141] OnExamination 2012 - Neurology

A 46-year-old father of three has just been diagnosed with Huntington's disease.

His oldest daughter is 21-years-old and thinking about starting a family soon.

He asks you what the chances are of his daughter also having Huntington's disease?

- 1- She will be a carrier as it is X linked.
- 2- She will definitely inherit it.
- 3- She will not have it as it is X linked
- 4- There is a 50% chance that she will have it
- 5- There is a 25% chance that she will have it.

Answer & Comments

Answer: 4- There is a 50% chance that she will have it

Huntington's disease is a neurodegenerative genetic disorder that is autosomal dominant.

Therefore she has a 50% chance of having the disease as she needs only to inherit one mutant gene, from her father.

The features are of choreiform movements, psychiatric illness and eventually dementia.

[Q: 4142] OnExamination 2012 - Neurology

A 78-year-old man presents to the Emergency Department with a right sided facial palsy affecting the whole of the right side of his face.

Of the following, which is the most likely cause?

- 1- Left sided infarct affecting the internal capsule
- 2- Left sided infarct affecting the frontal lobe
- 3- Right sided infarct affecting the internal capsule
- 4- Right sided seventh nerve palsy
- 5- Right sided fifth nerve palsy

Answer & Comments

Answer: 4- Right sided seventh nerve palsy

Upper motor neuron lesions tend to spare the forehead as it is bilaterally innervated. Forehead involvement suggests a lower motor neuron (LMN) lesion.

Regarding the options:

A, B and C are incorrect as forehead involvement suggests a LMN lesion.

D is correct as the forehead is involved. Muscles of facial expression are controlled by the seventh nerve.

E is incorrect as the fifth nerve does not innervate muscles of facial expression.

[Q: 4143] OnExamination 2012 - Neurology

A 70-year-old man presents with difficulty speaking.

He has a history of diabetes, hypertension, hypercholesterolaemia, chronic obstructive pulmonary disease. He is currently on aspirin, simvastatin, amlodipine and hydrochlorothiazide.

On examination the patient is awake, his blood pressure is 150/70 mmHg. His pulse is irregularly irregular.

He has 4/5 strength in the right arm and leg and 5/5 strength on the left. When asked to point to the window he does this correctly. When told to raise his arms and place his hands out he is seen to have a pronator drift on the right. He is shown a pen and asked what it is. His answer is unintelligible. He is asked to use it appropriately and begins to write on a piece of paper perfectly. When asked to repeat "Today is a sunny day", he attempts it but appears severely dysarthric and cannot be understood.

This type of dysphasia localises to?

- 1- Aphemia
- 2- Fluent aphasia
- 3- Non-fluent aphasia
- 4- Transcortical motor aphasia
- 5- Transcortical sensory aphasia

Answer & Comments

Answer: 1- Aphemia

In Wernicke's or fluent or receptive aphasia the patient is able to form correct grammatical sentences but language content is incorrect. It localises to the dominant superior temporal gyrus. There is poor comprehension and repetition but verbal output is fluent.

In Broca's or non-fluent or expressive aphasia the patient is unable to name objects with poor comprehension and repetition. It localises to the Broca's area in the left posterior inferior frontal gyrus.

In transcortical motor aphasia, which localises to the anterior superior frontal lobe, the patient has good comprehension and repetition but has halting, effortful speech. Patients also have impaired writing skills.

Transcortical sensory aphasia is what is described in this case. It is characterised by impaired auditory comprehension with intact repetition and fluent speech, and is caused by damage to the temporal lobes. It differs from Wernicke's aphasia in that patients still have intact repetition, and exhibit echolalia (the compulsive repetition of words). Improvement may be seen with speech therapy.

Aphemia is a type of aphasia in which there is severe dysarthria and impairment of verbal output. There is intact comprehension. It is believed to be the result of pars opercularis, inferior pre-Rolandic gyrus or subcortical lesions.

[Q: 4144] OnExamination 2012 - Neurology

A 70-year-old man presents with difficulty speaking.

He has a history of diabetes, hypertension, hypercholesterolaemia, chronic obstructive pulmonary disease. He is currently on aspirin, simvastatin, amlodipine and hydrochlorothiazide. On examination the patient is awake; his blood pressure is 150/70 mmHg. His pulse is irregularly irregular. He has 4/5 strength on the right arm and leg and 5/5 strength on the left.

When asked to point to the window he appears unable to do so. When told to raise his arms and place his hands out he does not. When visually shown the same action he is able to perform it. When asked to repeat 'Today is a sunny day', he is unable to do so. He appears frustrated and makes no intelligible words.

With what type of dysphasia is this consistent?

- 1- Broca's aphasia
- 2- Global aphasia
- 3- Transcortical motor aphasia
- 4- Transcortical sensory aphasia

5- Wernicke's aphasia

Answer & Comments

Answer: 2- Global aphasia

In Broca's or non-fluent or expressive aphasia the patient is unable to name objects with poor comprehension and repetition. It localises to the Broca's area in the left posterior inferior frontal gyrus.

In transcortical motor aphasia, which localises to the anterior superior frontal lobe, the patient has good comprehension and repetition but has halting, effortful speech. Patients also have impaired writing skills.

Transcortical sensory aphasia is characterised by impaired auditory comprehension with intact repetition and fluent speech, and is caused by damage to the temporal lobes. It differs from Wernicke's aphasia in that patients still have intact repetition, and exhibit echolalia (the compulsive repetition of words). Improvement may be seen with speech therapy.

In Wernicke's or fluent or receptive aphasia the patient is able to form correct grammatical sentences but language content is incorrect. It localises to the dominant superior temporal gyrus. There is poor comprehension and repetition but verbal output is fluent.

Global aphasia is what is described in this case. It results in an almost mute patient with deficits in all aspects of language: spontaneous speech, naming, repetition, auditory comprehension, reading and writing. Global aphasia is commonly seen in patients with large infarctions of the left cerebral hemisphere, usually due to occlusion of the internal carotid or middle cerebral artery. This results in resulting in damage of Broca's, Wernicke's and the arcuate fasciculus. It is also usually associated with right hemiplegia and right homonymous hemianopia, but it is increasingly recognised in isolation. The visual

centres remain intact and therefore patients are able to follow instructions shown to them.

[Q: 4145] OnExamination 2012 - Neurology

What is the mechanism of action of tetrabenazine?

- 1- Antimuscarinic
- 2- Monoamine oxidase inhibitor
- 3- Activates GABA_A receptors
- 4- Dihydropyridine calcium channel antagonist
- 5- VMAT inhibitor (vesicular monoamine transporter-2)

Answer & Comments

Answer: 5- VMAT inhibitor (vesicular monoamine transporter-2)

- A. Antimuscarinic drugs include trihexyphenidyl used in Parkinson's disease.
- B. Selegiline is a monoamine oxidase inhibitor used in Parkinson's disease.
- C. Benzodiazepines activate GABA_A receptors.
- D. Dihydropyridine calcium channel antagonists include amlodipine.

[Q: 4146] OnExamination 2012 - Neurology

A 62-year-old male presents with weakness of the right hand. You note global wasting of the small hand muscles, there is also sensory loss over the medial border of the forearm around the elbow.

Which nerve root is damaged?

- 1- C5
- 2- C6
- 3- C7

4- C8

5- T1

Answer & Comments**Answer:** 5- T1

This patient has Klumpke's paralysis due to damage to the T1 nerve root. This root eventually supplies the median and ulnar nerves.

The ulnar nerve supplies all of the intrinsic hand muscles except for those of the thenar eminence and the first and second lumbricals which are innervated by the median nerve.

[Q: 4147] OnExamination 2012 - Neurology

A 21-year-old male is admitted with acute onset headache and is drowsy. He is opening his eyes spontaneously, is disoriented and is localising painful stimuli. He has a normal computed tomography scan.

Which of the following is the next most appropriate investigation for this patient?

- 1- Cerebral angiography
- 2- Lumbar puncture
- 3- Magnetic resonance angiography
- 4- Magnetic resonance imaging
- 5- No further investigations necessary

Answer & Comments**Answer:** 2- Lumbar puncture

Lumbar puncture (LP) is not usually required unless the history is suggestive and the CT is normal as in this case. Blood will be present in the cerebral spinal fluid (CSF) (if a bloody tap is suspected the number of red blood cells should fall with each successive sample).

If the LP is performed six hours after onset of symptoms the supernatant fluid should be

examined for xanthochromia after centrifugation.

[Q: 4148] OnExamination 2012 - Neurology

A 21-year-old female is diagnosed with Guillain-Barre syndrome.

On examination her legs are areflexic and she has decreased sensation in her legs and arms.

What is the best investigation for monitoring respiratory function in this patient?

- 1- Chest expansion
- 2- FEV₁
- 3- FEV₁/FVC ratio
- 4- PEFR
- 5- Vital capacity

Answer & Comments**Answer:** 5- Vital capacity

Forced vital capacity (FVC) is very helpful in guiding disposition and therapy.

ITU admission is recommended when FVC is less than 20 mL/kg and intubation is recommended in most cases when FVC is less than 15 mL/kg.

[Q: 4149] OnExamination 2012 - Neurology

A 27-year-old woman presents to the Emergency department complaining of a diffuse headache for about a week. She says that her eyes have been 'going funny' every time she bends down to put on her shoes and she has vomited every morning for the past five days.

You notice that she frequently attends the Emergency department with minor problems - pelvic pain, low mood and most recently ear ache.

Which of the following is the most important diagnosis to consider?

- 1- Cerebral sinus thrombosis
- 2- Depression
- 3- Drug misuse
- 4- Otitis interna
- 5- Pregnancy

Answer & Comments

Answer: 1- Cerebral sinus thrombosis

This woman gives a history that is suspicious of raised intracranial pressure (ICP).

Vomiting in the morning is characteristic of raised ICP as it follows a period of lying flat.

Bending over causes a transient increase in already raised ICP. This further compresses the optic nerve and causes visual disturbance. Patients may also notice this when coughing or straining.

The patient's recent ear ache could have been a localised infection predisposing her to cerebral venous sinus thrombosis.

It is important not to dismiss immediately patients who frequently present with minor ailments.

A. This is the best answer (see above).

B. Depression is not the best answer. Depressed patients may present frequently with seemingly minor ailments, however in this case it would be important to rule out cerebral sinus thrombosis first.

C. Drug misuse is not the best answer. Patients who misuse drugs may present with multiple problems such as headache and vomiting. However, this history is suspicious for cerebral sinus thrombosis so this should be ruled out as a matter of urgency.

D. Otitis interna is not the best answer. This can cause headaches and vomiting and the patient may well have it as she was recently complaining of ear ache. However, this history is suspicious for cerebral sinus

thrombosis so this should be ruled out as a matter of urgency.

E. Pregnancy is not the best answer. Pregnant patients may well vomit in the morning and have vague headaches. However, this history is suspicious for cerebral sinus thrombosis so this should be ruled out as a matter of urgency.

[Q: 4150] OnExamination 2012 - Neurology

Hearing losses of a mild degree or worse (>25dB) are present in around 10% of the population. As the population ages, the percentage of people with hearing loss also increases.

Which of the following age-percentage loss combinations is not correct for the general population?

- 1- At birth approximately 0.3% affected
- 2- Aged 50-59: approximately 10% affected
- 3- Aged 60-69: approximately 25% affected
- 4- Aged 70-79: approximately 50% affected
- 5- Aged 80-89: approximately 50% affected

Answer & Comments

Answer: 5- Aged 80-89: approximately 50% affected

Percentage of the population with a significant hearing loss increases with each decade of life.

For the 80-89-year-old age group, around 70-80% of them will have a degree of hearing loss >25dB.

[Q: 4151] OnExamination 2012 - Neurology

A 65-year-old male presents with acute severe headache, ataxia and vomiting. Six hours later he became drowsy.

On examination he had left horizontal nystagmus, a partial left sixth cranial nerve palsy and extensor plantar responses. His blood pressure was 188/110 mmHg.

What is the most likely cause for this deterioration?

- 1- Brain stem herniation
- 2- Cerebral oedema
- 3- Dehydration
- 4- Malignant hypertension
- 5- Non-convulsive status epilepticus

Answer & Comments

Answer: 1- Brain stem herniation

The most likely explanation of the sudden deterioration will be brain stem herniation. The sudden onset of headache, ataxia and vomiting a few hours prior to this suggest that there may have been an intracranial haemorrhage which led to mass effect and subsequent herniation.

Brain herniation often causes false localising signs due to compression of various areas of the brain. There are various forms of herniation, which are outside the scope of this question. Simply, it usually follows two patterns: uncal herniation or central herniation.

Clinical presentation of uncal herniation includes a third nerve paresis (ipsilateral dilated pupil, abnormal external ocular movements, including nystagmus), contralateral hemiparesis, which can lead to ipsilateral hemiparesis. The third nerve paresis occurs due to compression of the parasympathetic fibres around the third nerve, which results in unopposed sympathetic response. Contralateral hemiparesis occurs with compression of the cerebral peduncle. Ipsilateral hemiparesis and third nerve palsy occur late when the lateral translation is so great that it compresses the contralateral third nerve and peduncle.

Central herniation usually presents with confusion and drowsiness, followed by impaired vertical gaze, small pupils, impaired oculoccephalic reflexes and bilateral corticospinal tract signs including increased tone and Babinski signs.

Additional signs are present due to raised intracranial pressure: bradycardia, hypertension, irregular breathing (Cushing response) and a sixth-nerve palsy. The sixth nerve is usually the first to be compressed due to its long extracerebral intracranial course.

Diplopia from either a third or sixth nerve palsy can cause nystagmus.

This patient needs immediate intensive care support, with intubation and hyperventilation. The case should be discussed urgently with neurosurgeons, and their advice sought regarding the possibility of operative intervention. Intravenous mannitol and other hyperosmolar solutions are often indicated, and should be considered.

Cerebral oedema could account for the sixth nerve palsy, nystagmus and hypertension, but the deterioration with impaired consciousness and extensor plantar responses should lead you to consider herniation as the cause.

Dehydration would not cause this constellation of neurological signs.

The blood pressure in malignant hypertension is typically higher than this (>220/120).

This history is not typical for status epilepticus.

[Q: 4152] OnExamination 2012 - Neurology

A 55-year-old man presents with a resting tremor of his right arm and a diagnosis of idiopathic Parkinson's disease is made.

Which one of the following drugs is most likely to help his tremor?

- 1- Amantadine
- 2- Benzhexol
- 3- Cabergoline
- 4- Co-careldopa
- 5- Selegiline

Answer & Comments

Answer: 2- Benzhexol

Anticholinergic treatment (for example, benzhexol) is the treatment of choice for tremor predominantly Parkinson's disease.

L-dopa and dopamine agonists are the treatment of choice for bradykinesia and rigidity.

[Q: 4153] OnExamination 2012 - Neurology

A 55-year-old man with alcohol dependency presents with a seizure which is attributed to alcohol withdrawal.

Which one of the following statements regarding these seizures is correct?

- 1- Long term diazepam therapy is indicated
- 2- Long term therapy with phenytoin is indicated
- 3- Seizures are likely to be accompanied by hallucinations
- 4- Seizures may be termed "alcoholic blackouts"
- 5- Seizures typically occur within 48 hours of alcohol withdrawal

Answer & Comments

Answer: 5- Seizures typically occur within 48 hours of alcohol withdrawal

Patients with a history of drug abuse are at high risk of developing seizures.

Such seizures occur characteristically within 48 hours of alcohol discontinuation (usually in the morning).

Long term therapy with antiepileptic treatment is not indicated in those patients.

CT brain is indicated in patients with suspected head injury and/or abnormal clotting screen, in order to exclude a subdural haematoma.

[Q: 4154] OnExamination 2012 - Neurology

A 35-year-old woman presents with pains in the right arm.

On examination she has wasting and weakness of the intrinsic muscles of the right hand, absent tendon reflexes in the right arm and impaired pinprick sensation in the right hand and forearm.

What is the most likely diagnosis?

- 1- Combined median and ulnar nerve lesions
- 2- Lower trunk brachial plexus lesion
- 3- Neuralgic amyotrophy
- 4- Syringomyelia
- 5- Thoracic outlet syndrome

Answer & Comments

Answer: 4- Syringomyelia

Median and ulnar nerve lesions would not cause absent reflexes in the arm.

Lower trunk brachial plexus (C8/T1) would not cause absent reflexes in the arm.

Neuralgic amyotrophy affects the upper plexus (C5-6) and therefore does not cause wasting of small muscles of hand.

Thoracic outlet syndrome will not cause absent reflexes.

Syringomyelia typically causes loss of reflexes, spinothalamic sensory loss, and weakness. It can be asymmetrical initially.

[Q: 4155] OnExamination 2012 - Neurology

A young woman who has suffered from cerebral venous sinus thrombosis associated with pregnancy is most likely to have been affected during which of the following periods?

- 1- During birth
- 2- In the 1st trimester
- 3- In the 2nd trimester
- 4- In the 3rd trimester
- 5- In the postpartum period

Answer & Comments

Answer: 5- In the postpartum period

Venous sinus thrombosis is associated with the oral contraceptive pill, the post partum period and other hypercoagulable states.

The clinical signs include

- Papilloedema
- Cranial nerves III, IV and VI
- Ocular chemosis and
- Proptosis.

[Q: 4156] OnExamination 2012 - Neurology

A 26-year-old male epileptic is admitted with temperature and rash.

Over the last one week a rash has developed and he has become increasingly ill. Recently he has had some problems with epileptic control and has commenced carbamazepine with valproate.

Examination reveals an unwell patient with a temperature of 39°C, a diffuse erythematous,

painful rash with evidence of some lateral sliding of these erythematous areas on palpation.

There is also blistering and inflammation of the oral cavity.

What is the likely diagnosis?

- 1- Erythema elevatum diutinum
- 2- Exfoliative dermatitis
- 3- Pustular psoriasis
- 4- Toxic epidermal necrolysis
- 5- Toxic shock syndrome

Answer & Comments

Answer: 4- Toxic epidermal necrolysis

This patient's presentation and clinical description suggests a diagnosis of toxic epidermal necrolysis (TEN) due to carbamazepine therapy.

TEN is a severe mucocutaneous exfoliative disease with an uncertain pathogenesis and a high mortality rate.

It is difficult to say whether it is another variant of Stevens-Johnson syndrome and treatment of both are similar.

It is often idiopathic but may be associated with:

Viral infections

Leukaemia

Lymphoma and

Drugs (in particular sulphonamides and anticonvulsants).

The suggested association with carbamazepine in this case makes toxic shock syndrome due to Staph. aureus remote, which like pustular psoriasis would not be expected to affect the mucous membranes.

[Q: 4157] OnExamination 2012 -
Neurology

An 80-year-old man presented to his GP having developed uncontrollable flinging movements of his right arm and leg in the last few days. He had been previously well prior to the event.

The movements were irregular involving the proximal limb muscles and did not follow a particular pattern. They occurred several times a minute and had led to several falls. He had a past medical history of hypertension and ischaemic heart disease and took regular ramipril and aspirin. He was a smoker of 10 cigarettes per day and did not drink any alcohol. There was no family history of neurological disease.

On examination he was alert and orientated, but had several episodes of flinging proximal movements of his right upper and lower limb that made examination difficult. Tone, power and reflexes all appeared normal and there were no obvious cranial nerve abnormalities. General examination revealed a blood pressure of 140/90mmHg, pulse of 78/min and regular and heart sounds were normal.

Investigations revealed:

Haemoglobin 15.2 g/dl (13.0 - 18.0 g/dL)

Mean cell volume 92 fL (80 - 96 fL)

White cell count $10.5 \times 10^9/L$ ($4 - 11 \times 10^9/L$)

Platelets $299 \times 10^9/L$ ($150 - 400 \times 10^9/L$)

Serum Sodium 135 mmol/L (137 - 144 mmol/L)

Serum Potassium 4.5 mmol/L (3.5 - 4.9 mmol/L)

Serum Urea 3.6 mmol/L (2.5 - 7.5 mmol/L)

Serum Creatinine 98 $\mu\text{mol/L}$ (60 - 110 $\mu\text{mol/L}$)

Fasting plasma glucose 8.9 mmol/L (3 - 6 mmol/L)

Serum cholesterol 6.2 mmol/L ($< 5.2 \text{ mmol/L}$)

What is the most likely diagnosis in this patient?

- 1- Functional disorder
- 2- Huntington disease
- 3- Infarction within the substantia nigra
- 4- Infarction within the subthalamic nucleus
- 5- Senile chorea

Answer & Comments

Answer: 4- Infarction within the subthalamic nucleus

The patient presents with a history in keeping with hemiballism.

The presence of severe flinging movements affecting proximal muscles and following no particular pattern is typical for hemiballism.

The site of the lesion is in the contralateral subthalamic nucleus, infarction being the commonest cause.

The patient has several arteriosclerotic risk factors including hypertension, hyperlipidaemia, ischaemic heart disease and diabetes.

Usually the flinging movements stop spontaneously in the next four to eight weeks and tetrabenazine is the treatment of choice.

Bilateral ballismus is rare and implicates a metabolic cause usually non-ketotic hyperosmolar coma.

[Q: 4158] OnExamination 2012 -
Neurology

A 73-year-old man presents with an abrupt onset of double vision and left leg weakness.

Examination shows weakness of abduction of the right eye and right-sided facial weakness affecting upper and lower parts of the face. He also has a left hemiparesis.

Where is the lesion?

- 1- Left frontal lobe
- 2- Left lateral medulla

- 3- Right corpus striatum
- 4- Right midbrain
- 5- Right pons

Answer & Comments

Answer: 5- Right pons

The abducens nucleus is next to the facial nucleus in pons.

They commonly co-exist in a pontine cerebrovascular accident (CVA).

Hemiparesis is also a common feature of pontine lesion.

[Q: 4159] OnExamination 2012 - Neurology

A 24-year-old man presents with a five month history of low back pain, radiating to his buttocks, and back stiffness worse in the morning and worse after periods of inactivity.

Which of the following signs is the most likely to be present?

- 1- Exaggerated lumbar lordosis
- 2- Positive femoral stretch test
- 3- Positive Trendelenburg test
- 4- Restricted straight leg raising
- 5- Sacroiliac joint tenderness

Answer & Comments

Answer: 5- Sacroiliac joint tenderness

This is a common presentation of ankylosing spondylitis.

The typical features are stiffness, first thing in the morning and after inactivity, and lower back pain radiating into the buttocks.

[Q: 4160] OnExamination 2012 - Neurology

A CT shows blood in the sylvian fissure.

In which compartment is this blood?

- 1- Epidural
- 2- Subarachnoid
- 3- Subcortical
- 4- Subdural
- 5- Subgaleal

Answer & Comments

Answer: 2- Subarachnoid

Subdural refers to the area between the dura and the arachnoid.

Epidural is between the skull and the dura.

Subgaleal is a potential space between the skull and the scalp aponeurosis.

Subcortical is in the white matter of the brain below the cortex.

[Q: 4161] OnExamination 2012 - Neurology

A 43-year-old woman develops a progressive, ascending motor weakness over several days.

She is hospitalised and requires intubation with mechanical ventilation. She is afebrile. A lumbar puncture is performed with normal opening pressure and yields clear, colourless cerebrospinal fluid (CSF) with normal glucose, increased protein, and cell count of 5/microlitre, all lymphocytes. She gradually recovers over the next month.

Which of the following conditions most likely preceded the onset of her illness?

- 1- Ketoacidosis
- 2- Staphylococcus aureus septicaemia
- 3- Systemic lupus erythematosus
- 4- Viral pneumonia
- 5- Vitamin B₁₂ deficiency

Answer & Comments

Answer: 4- Viral pneumonia

She has Guillain-Barre syndrome often preceded by an episode of infection such as viral (cytomegalovirus [CMV]) or bacterial (Campylobacter).

[Q: 4162] OnExamination 2012 - Neurology

A 72-year-old woman has a five year history of worsening mental functioning with trouble remembering things. She has no problems with movement.

She is noted on an MRI scan of the brain to have symmetrically increased size of the lateral ventricles along with cerebral cortical atrophy in a mainly frontal and parietal distribution.

A lumbar puncture reveals a normal opening pressure, and analysis of the clear, colorless cerebrospinal fluid (CSF) reveals glucose and protein which are in normal ranges.

Cell count on the CSF shows 3 WBCs (all lymphocytes) and 1 RBC.

A fundoscopic examination is normal.

Which of the following findings is most likely associated with her underlying disease process?

- 1- Increased numbers of Lewy bodies
- 2- Loss of Betz cells
- 3- Loss of gamma aminobutyric acid (GABA)
- 4- Perivascular mononuclear inflammation
- 5- Presence of the e4 allele of apolipoprotein E

Answer & Comments

Answer: 5- Presence of the e4 allele of apolipoprotein E

She has findings characteristic for Alzheimer's disease.

Loss of GABA is seen in Parkinson's disease.

Perivascular mononuclear inflammation is seen in multiple sclerosis.

Loss of Betz cells is seen in motor neurone disease.

[Q: 4163] OnExamination 2012 - Neurology

Which one of the following would support a diagnosis of subacute combined degeneration of the cord (SACDC) rather than multiple sclerosis (MS)?

- 1- Absent ankle jerks
- 2- Autonomic symptoms
- 3- Cerebellar signs
- 4- Extensor plantars
- 5- Visual problems

Answer & Comments

Answer: 1- Absent ankle jerks

The causes of absent ankle reflexes and extensor plantars include

Subacute combined degeneration of the cord (posterior column signs, positive Romberg's sign, anaemia, splenomegaly)

Syphilitic taboparesis

Friedreich's ataxia

Motor neurone disease.

Knee reflexes in SACDC may be increased, normal or absent.

In the latter stages of MS with marked muscle wasting, tendon jerks may be difficult to elicit.

All the other features may be common to both conditions - optic atrophy, cerebellar ataxia and spasticity.

The only tricky one is autonomic features because these are rare in both conditions. Remember MS affects the CNS whereas subacute combined degeneration of the cord affects central and peripheral nerves. That is the easiest way of answering the question.

[Q: 4164] OnExamination 2012 -
Neurology

Which of the following is correct concerning pseudotumour cerebri (benign intracranial hypertension)?

- 1- A mildly increased CSF cell count is typical.
- 2- Frequently presents with ataxia.
- 3- Is distinguished from hydrocephalus by the absence of suture separation.
- 4- Is typically associated with focal long tract signs.
- 5- May be caused by prolonged steroid therapy.

Answer & Comments

Answer: 5- May be caused by prolonged steroid therapy.

Pseudotumour cerebri is a clinical syndrome that mimics brain tumours, and is characterised by raised intracranial pressure with normal CSF cell count and protein content, normal ventricular size, anatomy and position.

Causes are:

Metabolic disorders: galactosaemia, hypoparathyroidism, pseudohyperparathyroidism, hypophosphatasia, steroid therapy, hypervitaminosis A, vitamin A deficiency, Addison's disease, obesity, menarche, oral contraceptives, pregnancy

Infections: Roseola infantum, chronic otitis media, mastoiditis, Guillain- Barré syndrome

Drugs: Nalidixic acid, tetracycline

Haematological disorders: Polycythaemia, haemolytic and iron deficiency anaemia, Wiskott-Aldrich syndrome

Destruction of intracranial drainage by venous thrombosis: Lateral sinus or posterior

sagittal sinus thrombosis, head injury, obstruction of the superior vena cava.

It usually presents with headache and vomiting, though this is rarely as bad as that associated with posterior fossa tumour.

Diplopia is common due to sixth nerve palsy. Children are alert with no systemic upset. A bulging fontanelle, cracked pot sounds, or separation of the cranial sutures may be present. Papilloedema with an enlarged blind spot is the most consistent sign beyond infancy.

Focal and neurological signs indicate a process other than pseudotumour cerebri. It may be complicated by optic atrophy and blindness.

Most can be treated conservatively with monitoring of visual acuity. For others, multiple lumbar punctures may be necessary to reduce intracranial pressure.

Very rarely are shunts required.

[Q: 4165] OnExamination 2012 -
Neurology

Which of the following is a characteristic feature of transient global amnesia?

- 1- Abnormal behaviour
- 2- Apraxia
- 3- Confabulation
- 4- Loss of personal identity
- 5- Normal perception

Answer & Comments

Answer: 5- Normal perception

Transient global amnesia (TGA) is a syndrome characterised by the abrupt onset of anterograde amnesia, accompanied by repetitive questioning. Patients are usually disoriented in time and place, but not usually person. They often recognise their disorientation. By definition, there are no

other neurological deficits. It usually occurs in middle-aged or elderly people, and attacks typically occur in the mornings and last minutes to hours (mean 6h). The attack is often associated with headache, nausea and dizziness. The ability to lay down new memories is gradually recovered, leaving only a dense amnesic gap for the duration of the episode (and often the hours prior to it). Recurrence is unusual.

Whilst clear-cut focal neurological signs are exclusion criteria for TGA, associated symptoms are commonly observed. The patient's behaviour during an attack may lead to them being described as confused. Other associated features are chills, fear of death, paraesthesia, emotional upset and chest pain.

Migraine may be a risk factor in younger patients (<55y). Psychological and vascular risk factors may also have a role. It has also been suggested that TGA may occur after a venous congestion in the context of insufficient jugular-vein valves.

'Characteristic' means that absence of the symptom would make you doubt the diagnosis. The presence of any of the other suggested options would suggest an alternative diagnosis.

[Q: 4166] OnExamination 2012 - Neurology

Which of the following would be expected features of a left posterior cerebral artery occlusion?

- 1- A right homonymous hemianopia
- 2- Decerebrate state
- 3- Internuclear ophthalmoplegia
- 4- Pure aphasia (that is, without alexia)
- 5- Wernicke's aphasia

Answer & Comments

Answer: 1- A right homonymous hemianopia

Internuclear ophthalmoplegia is typical of multiple sclerosis.

Wernicke's aphasia and pure aphasia (that is, without alexia) are middle cerebral artery.

Decerebrate state is most likely a pontine lesion.

Other possible findings in posterior left cerebral artery occlusion are:

Cortical blindness

Visual hallucinations

Thalamic syndrome

Claude's and Weber's syndromes.

[Q: 4167] OnExamination 2012 - Neurology

Which of the following is least likely to cause choreiform movements?

- 1- Polyarteritis nodosa (PAN)
- 2- Polycythaemia rubra vera
- 3- Rheumatic fever
- 4- Systemic lupus erythematosus
- 5- Thyrotoxicosis

Answer & Comments

Answer: 1- Polyarteritis nodosa (PAN)

PAN affects medium sized arteries and usually involves peripheral nerves, bowel and rarely lungs.

Other causes of chorea are Huntington's chorea, rheumatic fever and senile chorea.

[Q: 4168] OnExamination 2012 - Neurology

For which of the following could a right carotid artery stenosis not account?

- 1- Contralateral hemiplegia
- 2- Contralateral hemisensory loss

- 3- Drop attacks
- 4- Dysphasia
- 5- Right amaurosis fugax

Answer & Comments

Answer: 3- Drop attacks

Carotid artery disease causes

Contralateral hemiplegia

Hemisensory loss

Homonymous hemianopia

Dysphasia (right)

Hemineglect (left).

Drop attacks are due to vertebrobasilar insufficiency.

[Q: 4169] OnExamination 2012 - Neurology

A 30-year-old female presents to the eye clinic with an acute history of pain and blurring in the right eye.

Examination reveals a visual acuity of 6/36 in the right eye but 6/6 in the left eye, a central scotoma in the right eye, with a right swollen optic disc.

What is the most likely diagnosis?

- 1- Cavernous sinus thrombosis
- 2- Compression of the optic nerve
- 3- Glaucoma
- 4- Optic neuritis
- 5- Retinal vein occlusion

Answer & Comments

Answer: 4- Optic neuritis

The acute presentation with central scotoma, reduced visual acuity and a swollen optic disc in a young female suggests a diagnosis of multiple sclerosis with a retrobulbar neuritis.

[Q: 4170] OnExamination 2012 - Neurology

A 25-year-old female presented with six months history of depression, irritability and painful sensory symptoms in her legs. Over the last four weeks she presents a broad base ataxic gait.

An MRI brain showed bilateral posterior thalamic nuclei (pulvinar region) high signals.

Which of the following is the most likely diagnosis?

- 1- Herpes simplex encephalitis
- 2- Multiple system atrophy
- 3- New variant CJD
- 4- Sporadic CJD
- 5- Wilson disease

Answer & Comments

Answer: 3- New variant CJD

New variant Creutzfeldt-Jakob disease (CJD) usually presents in a young person, in their twenties or thirties.

In the majority of the cases the first symptoms are psychiatric and painful sensory symptoms in the lower limbs.

Ataxia and involuntary movements (for example, myoclonus) usually appear at an interval of about six months after the initial symptoms.

MRI brain shows bilateral pulvinar (posterior thalamic nuclei) high signals.

EEG is usually normal in new variant CJD.

[Q: 4171] OnExamination 2012 - Neurology

A 60-year-old male is referred with episodes of severe vertigo which may last up to four hours and are associated with vomiting and pain in the right ear.

On examination during an attack he is noted to have right horizontal nystagmus together with mild right-sided sensorineural deafness.

Which one of the following is the most likely diagnosis?

- 1- Acoustic neuroma
- 2- Benign positional vertigo
- 3- Labyrinthitis
- 4- Ménière's disease
- 5- Vertebrobasilar ischaemic attacks

Answer & Comments

Answer: 4- Ménière's disease

This is a typical history of Ménière's disease.

The attacks are paroxysmal, lasting hours and consist of

Vertigo

Vomiting

Pressure within the ear

Deafness.

After many attacks the patient may develop irreversible sensorineural deafness (of low frequency).

Prochlorperazine or cinnarizine usually helps vomiting, and restriction of salt and fluid may hasten resolution. Occasionally diuretics may be used but there is little evidence for efficacy.

[Q: 4172] OnExamination 2012 - Neurology

A 70-year-old female patient presents with two months history of apathy, withdrawal, urinary and faecal incontinence and anosmia.

Of the following where is the most likely anatomical site of the neurological lesion?

- 1- Frontal lobe
- 2- Internal capsule

- 3- Occipital lobe
- 4- Parietal lobe
- 5- Temporal lobe

Answer & Comments

Answer: 1- Frontal lobe

Frontal lobe syndrome usually presents with:

Personality changes

Urinary and faecal incontinence

Anosmia

Expressive dysphasia (dominant lobe)

Release of primitive reflexes (positive grasp, pout and palmomental reflexes)

Epilepsy.

Fifty per cent of patients presenting with status epilepticus (with no previous history of seizures) have frontal lobe tumour.

It can mimic dementia.

[Q: 4173] OnExamination 2012 - Neurology

A 54-year-old Somali lady presents with weakness of her lower limbs.

Four months ago she had noticed weakness of her left leg and this has steadily progressed to affect both legs.

On examination she has multiple bruises of different ages on her legs and body. She has reduced power bilaterally with hyperreflexia, an ataxic gait and head tremor. Her family have noticed her behaving abnormally recently, disinhibited with poor short term memory.

What is the most likely causative agent?

- 1- Cryptococcus neoformans
- 2- Human immunodeficiency virus 1
- 3- Human immunodeficiency virus 2
- 4- JC virus

5- Toxoplasma gondii

Answer & Comments

Answer: 4- JC virus

This lady has progressive multifocal leukoencephalopathy (PML).

The features are:

Behavioural changes

Ataxia

Head tremor

Focal neurology progressing over a period of months to paresis and even coma.

It can be diagnosed via CSF PCR for the JC virus.

Cryptococcus neoformans causes meningitis in HIV positive patients. Patients present with headache, fever, vomiting and few neurological signs.

Toxoplasmosis presents with headache, fever and seizures. They have a typical CT head scan with ring enhancing lesions.

HIV 1 or 2 are the underlying infections making this lady susceptible to other organisms; however it is the JC virus that is making her unwell at this presentation.

PML can present at any CD4 count.

HIV infection can cause dementia, however this progresses over a longer time period. Symptoms are of confusion, depression, reduced concentration, behavioural changes, speech and balance problems as well as muscle weakness.

[Q: 4174] OnExamination 2012 - Neurology

An 18-year-old presents with her third 'funny turn'.

She was witnessed smacking her lips and making repetitive chewing movements. She

recalls a rising epigastric sensation preceding this, but was unaware of what she was doing.

Which of the following would you suspect?

1- Absence seizures

2- Frontal lobe epilepsy

3- Migraine

4- Temporal lobe epilepsy

5- Transient ischaemic attack

Answer & Comments

Answer: 4- Temporal lobe epilepsy

This is a classic description of temporal lobe epilepsy. The commonest finding is hippocampal sclerosis and an MRI is an appropriate investigation.

Spread of the seizure activity to the contralateral temporal lobe impairs memory of the event in the complex partial form of temporal lobe epilepsy.

Regarding the options:

A is incorrect as there are repetitive movements involved.

B is incorrect as it does not tend to involve repetitive mouth movements or gastric rising.

C is incorrect as there is no headache and there is memory loss.

D is correct as temporal lobe epilepsy can present with gastric rising and repetitive mouth movements.

E is incorrect as there is not a sudden onset of focal neurology.

[Q: 4175] OnExamination 2012 - Neurology

A 20-year-old presents to the emergency room having experienced altered mental state for several days. There is no travel history reported.

She is arousable but appears confused. She has spontaneous movements of the limbs which are erratic and non-rhythmical and last a second.

She has reported difficulty in concentration and headaches recently. A head CT is obtained which is normal and a lumbar puncture shows normal protein, glucose and no white cells or red cells.

Laboratory results include a normochromic normocytic anaemia, elevated TSH, normal electrolytes and renal function, normal coagulation and liver studies. Serum and urine toxicology is negative. HIV screen is negative.

She has no history of drug or alcohol abuse. Pregnancy test was negative.

Which of the following laboratory tests should be ordered based on the history?

- 1- Anti-thyroid peroxidase antibodies
- 2- Gamma gluconyl transferase
- 3- Peripheral/blood smear
- 4- Prealbumin
- 5- Thyroglobulin level

Answer & Comments

Answer: 1- Anti-thyroid peroxidase antibodies

Gamma gluconyl transferase would not change the management as the drug screen was negative and liver function tests are normal.

Prealbumin is a marker of nutritional status but would not be important at this time, and albumin was reported normal.

Thyroglobulin levels would not change management; however antibodies to thyroglobulin can be present in Hashimoto's encephalopathy.

Peripheral or blood smear may be chosen because of the anaemia however given this is a normocytic normochromic anaemia it is

likely the result of iron loss through menstruation.

[Q: 4176] OnExamination 2012 - Neurology

A mother comes to your office concerned about her 2-year-old son. She has noticed that he typically laughs inappropriately for no particular reason. Shortly after an event he appears to be fidgeting. These events last only minutes and in between the events he acts normally.

What is your suspected diagnosis?

- 1- Gelastic seizures
- 2- Malingering
- 3- Pseudobulbar affect
- 4- Substance abuse
- 5- Tourette's

Answer & Comments

Answer: 1- Gelastic seizures

Gelastic seizures should be suspected in cases of erratic laughing or crying. It can be hard to identify in young children but there is usually associated automatisms such as fidgeting or lip smacking or change in sensorium.

Pseudobulbar affect can also present with inappropriate affective responses but typically occurs in adult patients with brainstem or frontal disease. It can be seen in multiple sclerosis or motor neuron disease.

The vignette is not typical for a tic disorder and it is unlikely a 2-year-old is malingering or abusing substances.

[Q: 4177] OnExamination 2012 - Neurology

Against which of the following is the specific antibody found in neuromyelitis optica?

- 1- Aquaporin 4
- 2- Glial fibrillary acidic protein

- 3- Myelin basic protein
- 4- Oligoclonal bands
- 5- Transthyretin

Answer & Comments

Answer: 1- Aquaporin 4

Myelin basic protein is elevated in demyelinating disease and is non-specific.

Oligoclonal bands are elevated in inflammatory responses and again are non-specific.

Glial fibrillary acidic protein is used to stain glial cells in immunohistochemistry.

Transthyretin mutations are seen in amyloidosis.

[Q: 4178] OnExamination 2012 - Neurology

A 30-year-old woman presents with problems seeing for the past two days.

She reports that the vision of her left eye is much worse than normal for the last two days. She reports that she woke up and thought there was something in her eye but the vision is getting worse. She denies diplopia but has blurred vision.

On examination her visual acuity is 20/20 in the right eye and finger counting only in the left. There is red desaturation and a relative afferent papillary defect. Her past medical history is unremarkable and she reports never having had neurological symptoms in the past.

On examination of her fundus, what is the most likely finding?

- 1- Cupped disc
- 2- Macular star
- 3- Normal optic disc
- 4- Optic atrophy
- 5- Papilloedema

Answer & Comments

Answer: 3- Normal optic disc

The patient has a clinically isolated syndrome presenting as retrobulbar neuritis. The concern for the patient to develop MS would be high given this initial presentation.

Optic atrophy occurs over a longer period of time.

Papilloedema suggests increased intracranial pressure.

A macular star is a finding seen in some inflammatory diseases but not in optic neuritis.

A cupped disc is seen in glaucoma.

[Q: 4179] OnExamination 2012 - Neurology

A 60-year-old man presented with an episode of right sided weakness that lasted 10 minutes and fully resolved.

Examination reveals that he is in atrial fibrillation.

Assuming he remains in atrial fibrillation which of the following is the most appropriate management regime?

- 1- Aspirin
- 2- No additional drug treatment
- 3- Warfarin, INR range 2 - 3
- 4- Warfarin, INR range 2 - 3 for six months then aspirin
- 5- Warfarin, INR range 3 - 4

Answer & Comments

Answer: 3- Warfarin, INR range 2 - 3

This is a high risk patient for future stroke and should be anticoagulated with warfarin.

An initial target range of international normalised ratio (INR) 2 - 3 is the most appropriate.

[Q: 4180] OnExamination 2012 -
Neurology

A 32-year-old shop worker presents with a 24 hour history of weakness in the hands. She also complains of shortness of breath.

The oxygen saturations are 90% on air. The biceps and triceps reflexes are absent in the left arm and reduced in the right arm.

Which of the following are recognised treatments of this acute presentation?

- 1- Edrophonium
- 2- G-CSF
- 3- Non-steroidal anti-inflammatory drugs
- 4- Physiotherapy
- 5- Plasmapheresis

Answer & Comments

Answer: 5- Plasmapheresis

This young woman has features suggestive of Guillan-Barre syndrome. Classically muscular weakness usually begins in the leg, and ascends to involve the trunk, arms and cranial nerves. However, increasingly clinical variants are being recognised in which weakness initially begins in other areas, including the hands. Early initiation of immunosuppressive treatment has been shown to lead to a good prognosis in these cases.

One important consideration is the monitoring of vital capacity and appropriate management in an environment where intubation can be undertaken rapidly. Specific therapy which can be initiated are plasmapheresis (plasma exchange) and high-dose intravenous immunoglobulin (IVIG) therapy. In UK clinical practice, IVIG is used more frequently as it is easier to administer. Corticosteroids have been linked with worsening of symptoms. Passive physiotherapy is critical whilst weakness persists, progressing to active exercise when the weakness begins to resolve. However,

this does not have an effect on the course of disease.

There is no evidence for the use of non-steroidal anti-inflammatory drugs.

G-CSF is used in neutropenia.

Edrophonium is a reversible acetylcholinesterase inhibitor, which can be used to diagnose myasthenia gravis (although this is rarely done in clinical practice).

[Q: 4181] OnExamination 2012 -
Neurology

A 36-year-old female presents with a six month history of having problems sleeping at night.

She has been woken on numerous occasions by her legs which are irritable and feel that they are being tugged. She needs to keep moving them. This urge lasts for variable periods and she finds little relief from rubbing the legs. No abnormalities are noted on examination of her legs.

Which of the following is the most appropriate treatment for this patient?

- 1- Amitriptyline
- 2- Gabapentin
- 3- Psychiatric referral
- 4- Ropinirole
- 5- Venlafaxine

Answer & Comments

Answer: 4- Ropinirole

This patient has features of restless legs syndrome (RLS). Typically there is an uncomfortable sensation in the legs and a feeling of needing to move them.

The exact aetiology is unknown. Although no specific tests exist for the diagnosis it is based on the International Restless Legs Syndrome Study Group four basic criteria for diagnosing RLS:

A desire to move the limbs, often associated with paraesthesias or dysaesthesias

Symptoms that are worse or present only during rest and are partially or temporarily relieved by activity

Motor restlessness, and

Nocturnal worsening of symptoms.

Treatment depends on the severity of the problem and the most appropriate treatment here would be ropinirole, which is the only agent licensed for this purpose.

[Q: 4182] OnExamination 2012 - Neurology

A 34-year-old male presents with back pain and weakness.

Which of the following would support a diagnosis of prolapsed intervertebral disc?

- 1- Bilateral symmetrical nerve involvement
- 2- Loss of sensation over the left outer upper thigh
- 3- No evidence of nerve compression
- 4- Pain which is unremitting in character
- 5- Pain which is worse on resting

Answer & Comments

Answer: 2- Loss of sensation over the left outer upper thigh

Prolapsed intervertebral disc is associated with pain and neurological loss in one nerve root.

Frequently roots of the sciatic nerve are affected.

Compression of more than one root suggests an alternative diagnosis.

Pain at rest would suggest an alternative diagnosis such as infection, tumour or metabolic disease, as would unremitting pain.

[Q: 4183] OnExamination 2012 - Neurology

A 21-year-old male is admitted with acute onset headache and is drowsy.

He is opening his eyes spontaneously, is disoriented but is localising to painful stimuli.

Which of the following is the investigation of choice for this man?

- 1- Computed tomography (CT)
- 2- Lumbar puncture (LP)
- 3- Magnetic resonance angiography (MRA)
- 4- Magnetic resonance imaging (MRI)
- 5- Positron emission tomography (PET)

Answer & Comments

Answer: 1- Computed tomography (CT)

Urgent CT will confirm diagnosis in 95% of patients with subarachnoid haemorrhage.

Lumbar puncture is not usually required unless the history is suggestive and the CT is normal.

Blood will be present in the cerebro-spinal fluid (if a bloody tap is suspected the number of red blood cells should fall with each successive sample).

If the LP is performed six hours after onset of symptoms the supernatant fluid should be examined for xanthochromia after centrifugation.

[Q: 4184] OnExamination 2012 - Neurology

A 59-year-old female pub landlady presents with acute, severe lumbar back pain.

There is no history of orthopaedic problems and until this event she had been in perfect health.

The patient complains of paraesthesia in the lower limbs and on further questioning has not voided urine since the onset of the pain.

Neurological examination reveals weakness (3/5 of both lower limbs, loss of sensation in L4, L5 and S1). Vibration sensation and joint position sensation is preserved. Reflexes in the ankles and knees are absent and the plantar response is equivocal.

The blood pressure is 158/68 mmHg, heart rate 95 bpm, temperature 36.9°C and ECG shows normal sinus rhythm with no ischaemic changes.

The remainder of the examination is normal.

Which of the following should be undertaken next for this patient?

- 1- CT head
- 2- Duplex scan of aorta
- 3- MRI spinal cord
- 4- Rectal examination
- 5- USS abdomen

Answer & Comments

Answer: 3- MRI spinal cord

This patient has a number of features of cauda equina syndrome. There is distal weakness, with associated sensory loss. Whilst classically patients present with a sensory level, this is variable in clinical practice.

Causes of cauda equina syndrome include herniation of a lumbar disc (at L4/L5 and L5/S1), tumour (metastases, lymphoma, primary spinal tumours), trauma and infection (epidural abscess).

Clinical presentation is varied, but can include low back pain with unilateral or bilateral lower limb motor and/or sensory abnormality and bowel and/or bladder dysfunction with saddle and perineal anaesthesia.

MRI is the investigation of choice to confirm the diagnosis and determine the level of compression and underlying cause. Delayed diagnosis and intervention can lead to permanent neurological damage, and

therefore MRI should be undertaken in a timely fashion.

Determining the presence of bowel dysfunction (with reduced anal tone and sensation) can be helpful prognostically, but does not assist with the differential diagnosis.

The pattern of weakness is not consistent with an intracranial cause, and USS abdomen or duplex scan of the aorta are unlikely to help here.

[Q: 4185] OnExamination 2012 - Neurology

A 78-year-old male is brought to the Emergency department and has a witnessed seizure in the resuscitation room.

His blood glucose is recorded as 1.0 mmol/l. He does not have diabetes, and has no other significant past medical history.

He is given 50 ml of 50% dextrose and he slowly recovers over the next one hour. A serum cortisol concentration later returns as 800 nmol/l (120-600).

Which of the following would be the most relevant investigation for this man?

- 1- Chest x ray
- 2- CT head scan
- 3- Electrocardiogram
- 4- Prolonged 72 hour fast
- 5- Short Synacthen test

Answer & Comments

Answer: 4- Prolonged 72 hour fast

The historical and biochemical evidence here suggests a diagnosis of spontaneous hypoglycaemia, and the most likely cause would be an insulinoma. However, one would wish to exclude possible drug administration and although not mentioned here, a sulphonylurea screen should be undertaken.

He has presented with symptomatic hypoglycaemia, is not diabetic and therefore should not have received insulin or a sulphonylurea.

There is nothing to suggest alcohol or drug misuse. Similarly, there is nothing to suggest sepsis.

However, to prove a diagnosis of spontaneous hypoglycaemia, a prolonged fast is required and should he develop hypoglycaemia, measurement of insulin and C peptide will be needed to confirm the diagnosis.

The appropriate cortisol response during his hypoglycaemic episode (cortisol 800) excludes hypoadrenalism.

[Q: 4186] OnExamination 2012 - Neurology

What is the agent responsible for variant Creutzfeldt-Jakob disease (CJD)?

- 1- Mutant mitochondrial DNA
- 2- Non-protein transmissible pathogen
- 3- Proteinaceous infectious particle
- 4- Retrovirus
- 5- Slow virus

Answer & Comments

Answer: 3- Proteinaceous infectious particle

Variant CJD is a transmissible spongiform encephalopathy. It is associated with the accumulation of an abnormal isoform of a normal host protein (prion protein) in the central nervous system.

This prion protein has no sequence differences from the normal protein, being encoded by the same normal host gene, but there is a major difference in the conformation of the two forms with the prion protein containing less helix structure.

The predominance of this structure confers a remarkable resistance to degradation and allows the protein to accumulate within the central nervous system.

[Q: 4187] OnExamination 2012 - Neurology

A 35-year-old male presents with a 12 month history of involuntary movements of his limbs.

Examination revealed generalised chorea but otherwise no neurological abnormalities.

Involvement of which of the following structures is likely to cause this presentation?

- 1- Caudate nucleus
- 2- Hippocampus
- 3- Lateral geniculate nucleus
- 4- Red nucleus
- 5- Substantia nigra

Answer & Comments

Answer: 1- Caudate nucleus

Caudate nucleus pathology is associated with chorea (for example, in Huntington's disease).

Hippocampus pathology is associated with short term memory impairment (for example, Alzheimer's disease).

Lateral geniculate nucleus pathology causes a visual field defect.

Red nucleus is associated with tremor, which is present both at rest and during action (for example, multiple sclerosis tremor).

Substantia nigra pathology is associated with Parkinson's disease.

[Q: 4188] OnExamination 2012 - Neurology

An 81-year-old female is admitted following a seizure although her relatives state that prior

to this she had been increasingly confused, unsteady and unable to look after herself over the last two to three weeks.

On examination she was drowsy and had a temperature of 37.5°C, and a blood pressure of 192/108 mmHg.

She had a mixed aphasia, with a mild right hemiparesis.

What is the most likely diagnosis?

- 1- Acute cerebral infarction
- 2- Acute intracerebral haemorrhage
- 3- Cerebral abscess
- 4- Chronic subdural haematoma
- 5- Glioblastoma

Answer & Comments

Answer: 4- Chronic subdural haematoma

The history of variable 'confusion' and unsteadiness for some weeks followed by an acute exacerbation is a typical presentation of a subdural haematoma in the elderly population.

Cerebral abscess is unlikely due to the absence of significant fever.

Acute infarction or acute intracerebral haemorrhage would not explain the two week history of confusion and unsteadiness.

Astrocytoma usually causes symptoms over months to years.

Mixed aphasia (or transcortical mixed aphasia) is, simply, not a complete 'global aphasia'. In global aphasia there is receptive and expressive dysphasia.

Patients can often repeat words but not understand commands, name objects or have intelligible spontaneous speech.

'Mixed aphasia' is not specific for stroke, although it can be caused by it. It may be caused by

Alzheimer's disease

Bilateral cerebral damage

Tumours

Thalamic lesions

and so on.

It is an excellent choice of language defect for a 'best of five' question since it is a good distractor.

[Q: 4189] OnExamination 2012 - Neurology

A 45-year-old man presented with a three day history of headache and increasing confusion.

On examination he was febrile with marked neck stiffness.

Investigations revealed:

Cerebrospinal fluid analysis (normal ranges are shown in brackets):

White cell count 600/ml (<5)

White cell differential >90% Neutrophils

Gram stain Gram-negative diplococci

Which one of the following antibiotics, given intravenously, is the most appropriate treatment?

- 1- Ampicillin
- 2- Benzylpenicillin
- 3- Cefuroxime
- 4- Ciprofloxacin
- 5- Gentamicin

Answer & Comments

Answer: 2- Benzylpenicillin

This is clearly a case of meningococcal meningitis. The commonest causes of bacterial meningitis in adults are:

Neisseria meningitidis (Gram negative diplococci)

Streptococcus pneumoniae (Gram positive diplococci).

Treatment of bacterial meningitis

On the basis of Gram stain results:

Gram stain unavailable or no stainable organisms: Cefotaxime ± ampicillin

Gram positive cocci: Cefotaxime + vancomycin

Gram positive bacilli: Ampicillin + gentamicin

Gram negative cocci: Benzylpenicillin (penicillin G)

Gram negative bacilli: Cefotaxime + gentamicin.

On the basis of CSF culture:

Streptococcus pneumoniae

If penicillin MIC <0.06 µgrams/mL: Benzylpenicillin (penicillin G) or cefotaxime

If penicillin MIC >0.1 µgrams/mL (that is, penicillin-resistant pneumococcus): Cefotaxime (+ vancomycin if susceptibility to broad-spectrum cephalosporins reduced)

Neisseria meningitidis: Benzylpenicillin (penicillin G)

Haemophilus influenzae: Cefotaxime

Listeria monocytogenes: Ampicillin + gentamicin

Group B streptococcus: Benzylpenicillin (penicillin G).

[Q: 4190] OnExamination 2012 - Neurology

A 25-year-old-man presented with severe headache, myalgia and a blanching red macular rash. He had returned from Indonesia three days previously.

On examination his blood pressure was 75/50 mmHg. A diagnosis of dengue fever was made.

Which of the following would be given immediately?

1- A single dose of ivermectin

2- Intravenous hydrocortisone 200 mg

3- Intravenous normal saline

4- Metronidazole

5- Tetracycline

Answer & Comments

Answer: 3- Intravenous normal saline

Dengue is transmitted by *Aedes aegypti* mosquito in endemic areas.

There are four serotypes.

Re-infection with a different serotype aggravates the infection and is associated with serious complications such as dengue haemorrhagic fever (DHF) and dengue shock syndrome (DSS). Treatment is supportive with fluid replacement, blood transfusion and correction of clotting.

Corticosteroids have no role.

In the first few days the rash is macular, blanching and transient. The second rash which looks like measles and is morbilliform, maculopapular, sparing palms and soles.

Do not confuse dengue fever with dengue haemorrhagic fever. Medline Plus

[Q: 4191] OnExamination 2012 - Neurology

A 16-year-old male presents with a five year history of absence seizures with three recent generalised convulsions.

Which one of the following drugs, given as monotherapy, is most likely to control his fits?

1- Clonazepam

2- Ethosuximide

3- Gabapentin

4- Sodium valproate

5- Topiramate

Answer & Comments

Answer: 4- Sodium valproate

Absences, generalised tonic clonic seizures and myoclonus are features of primary generalised epilepsy.

The treatment of choice includes sodium valproate, lamotrigine and topiramate.

Clonazepam is useful in myoclonus, ethosuximide in isolated absences and gabapentin in partial seizures.

Valproate would be the most appropriate first line agent.

[Q: 4192] OnExamination 2012 - Neurology

A 16-year-old boy presents with rapidly progressive weakness over three days, which is attributed to Guillain-Barré syndrome.

Which one of the following is the most appropriate treatment?

- 1- Azathioprine
- 2- Cyclosporin
- 3- Immunoglobulin
- 4- Methotrexate
- 5- Methylprednisolone

Answer & Comments

Answer: 3- Immunoglobulin

Randomised controlled trials have shown that human immunoglobulins and plasma exchange improve outcome in Guillain-Barré syndrome (GBS).

Other immunosuppressive treatment does not have a role in the treatment of GBS.

[Q: 4193] OnExamination 2012 - Neurology

A 24-year-old law student attends with visual loss affecting the right eye. She reports a constant headache for the last three months, and absence of menses for six months.

On examination her visual acuity in the right eye is 6/24, with slight constriction of the temporal field in that eye but she has no other neurological deficit. She is afebrile and haemodynamically stable.

What is the diagnosis?

- 1- Glaucoma
- 2- Migraine
- 3- Multiple sclerosis
- 4- Pituitary tumour
- 5- Pregnancy

Answer & Comments

Answer: 4- Pituitary tumour

This patient has a pituitary lesion; the history of headache and amenorrhoea suggests a prolactinoma or non-functioning tumour. This has been complicated by involvement of the visual pathway, which has precipitated her visual loss.

She needs urgent assessment of her pituitary function, imaging of the pituitary gland by MRI scanning.

One of the most important investigations to perform would be a serum prolactin.

The amenorrhoea would argue against this being retrobulbar neuritis associated with MS and similarly the peripheral visual field constriction would be unusual as a central scotoma and fluctuating visual loss would be more typical.

[Q: 4194] OnExamination 2012 - Neurology

A 70-year-old woman presented with an

acute, severe occipital headache, unsteadiness of her gait and vomiting. She had a history of poorly controlled hypertension.

On examination there was nystagmus to the left, ataxia of the left limbs and gait ataxia.

What is the most likely diagnosis?

- 1- Acute cerebellar haemorrhage
- 2- Basal ganglia haemorrhage
- 3- Pontine haemorrhage
- 4- Subdural haemorrhage
- 5- Temporal lobe haemorrhage

Answer & Comments

Answer: 1- Acute cerebellar haemorrhage

Cerebellar haemorrhage

The most common symptoms are of severe nausea and vomiting and ataxia. Headache may be severe. Patients with cerebellar haemorrhage can rapidly become comatose within hours after the onset from herniation, because of its limited space in the posterior fossa.

Pontine haemorrhage

There are numerous nuclei located within the pons. Rapidly deteriorating level of consciousness, impaired extraocular movement and extensive sensorimotor deficits are clinical clues to pontine haemorrhage.

Basal ganglia haemorrhage

Contralateral hemiparesis, hemisensory loss, or hemi-inattention. Aphasia, especially non-fluency and impaired comprehension, is frequently seen if haemorrhage occurs in the posterior limb of the left internal capsule.

[Q: 4195] OnExamination 2012 - Neurology

A 56-year-old female presented to her GP

with pain in the left side of her neck radiating down the lateral aspect of her arm and forearm.

She had also noticed some weakness of her left shoulder and struggled to elevate her arm. She had a longstanding history of rheumatoid arthritis, treated with steroids and penicillamine. She was a non-smoker and did not drink any alcohol.

On examination there was some wasting over the left deltoid and evidence of fasciculations. Neck movements appeared full except that lateral movement exacerbated the left arm pain.

On examination of the upper limb, tone appeared reduced at the elbow and wrist and the biceps jerk was only present on re-enforcement. The left supinator jerk was inverted and the triceps jerk appeared brisk. There was some weakness of left shoulder abduction, elbow flexion and supination, but finger movements and elbow extension were intact. There was a sensory deficit over the lateral aspect of the left upper arm and forearm. The right arm appeared normal.

On examination of the lower limb, tone was increased, but power appeared normal. All reflexes were brisk and both plantar responses were extensor.

Investigations showed:

Haemoglobin 11.4 g/dl (13.0-18.0 g/dl)

White cell count $3.4 \times 10^9/L$ ($4-11 \times 10^9/L$)

Platelets $245 \times 10^9/L$ ($150-400 \times 10^9/L$)

ESR (Westergren) 45 mm/1st hour (0-15 mm/1st hour)

Serum Sodium 145 mmol/L (137-144 mmol/L)

Serum Potassium 3.2 mmol/L (3.5-4.9)

Serum urea 6.7 mmol/L (2.5-5 mmol/L)

Serum Creatinine 135 $\mu\text{mol/L}$ (60-110 $\mu\text{mol/L}$)

Serum creatine kinase 178 U/L (24-170 U/L)

Fasting plasma glucose 8.7 mmol/L (3-6 mmol/L)

What is the most likely diagnosis?

- 1- Cervical myelopathy
- 2- Circumflex neuropathy
- 3- Inclusion body myositis
- 4- Motor neurone disease
- 5- Steroid-induced myopathy

Answer & Comments

Answer: 1- Cervical myelopathy

This patient has a cervical myelopathy, most likely as a result of her rheumatoid arthritis.

The likely level is C5/C6 given that there is weakness of the deltoid, biceps and supinator and the supinator jerk is inverted.

She also has long tract signs in her legs with hypertonia and hyperreflexia.

A circumflex neuropathy would account for the weakness and fasciculations of the deltoid, but would not explain the upper motor neurone signs in the legs, or weakness of the biceps and supinator.

Inclusion body myositis, an inflammatory myopathy, would present with bilateral often asymmetrical weakness, which has a tendency to affect distal musculature. The tendon reflexes would be normal and the creatine kinase would be normal or mildly elevated.

Motor neurone disease presents with upper and lower motor signs in absence of sensory disturbance.

A steroid induced myopathy would cause proximal weakness and wasting with normal reflexes and sensation.

[Q: 4196] OnExamination 2012 - Neurology

A 22-year-old man suffers a deep laceration to the forearm resulting in transection of the median nerve.

Following this injury, the nerve will undergo which of the following pathological processes?

- 1- Chronic inflammation
- 2- Coagulative necrosis
- 3- Fibrinoid necrosis
- 4- Segmental demyelination
- 5- Wallerian degeneration

Answer & Comments

Answer: 5- Wallerian degeneration

Wallerian degeneration is degeneration of the portion of the nerve distal to the injury. It occurs following axonal injury in both the peripheral and central nervous systems and usually begins within 24-36 hours of injury.

Coagulative necrosis is cell death following ischaemia or infarction. It is characterised by a 'ghostly' appearance of affected cells under light microscopy.

Fibrinoid necrosis is a form of necrosis in which there is an accumulation of material in the affected tissue with a staining pattern reminiscent of fibrin. It is associated with Henoch-Schönlein purpura, malignant hypertension and hyperacute transplant rejection.

Segmental demyelination is a feature seen in axons in the central nervous system with multiple sclerosis.

[Q: 4197] OnExamination 2012 - Neurology

Which of the following is true regarding sensory neural hearing loss?

- 1- Approximately 1 per 1000 children will have greater than 40db hearing loss.
- 2- The incidence is half as high in babies admitted to neonatal intensive care units compared with the normal population.

- 3- The risk is increased in children who have had post-natal rubella.
- 4- The risk is increased in Down's syndrome.
- 5- The risk is increased in Werdnig-Hoffman syndrome.

Answer & Comments

Answer: 1- Approximately 1 per 1000 children will have greater than 40db hearing loss.

Sensory neural hearing loss is caused by lesions in the cochlea or the auditory nerve or central connections. It may be unilateral or bilateral. Language acquisition and secondary educational difficulties follow, with social isolation, and an increased risk of mental health problems. The approximate incidence is 1 per 1000 children.

Risk factors include:

Neonatal intensive-care unit (NICU) admission: low birth weight, less than 32 weeks gestation, prolonged ventilation, prolonged jaundice, ototoxic drugs, hypoxic ischaemic encephalopathy, neonatal meningitis

Congenital infection (rubella, cytomegalovirus [CMV])

Dysmorphic syndromes (affecting head and neck)

Family history of a close relative needing a hearing aid below the age of 5 years

Infections: acute bacterial or TB meningitis, mumps (latter usually unilateral).

If all risk factors are considered, only around 50% of cases could be identified by testing between 5 and 10% of all babies.

Conductive hearing loss is related to middle ear pathology. This is commoner in Down's syndrome, cleft palate, Turner's syndrome, and facial malformation syndromes.

Werdnig-Hoffman is associated with normal hearing.

[Q: 4198] OnExamination 2012 - Neurology

A 35-year-old female presents with headaches.

Examination reveals papilloedema.

Which of the following would make the diagnosis of benign intracranial hypertension (BIH) unlikely?

- 1- Absence of retinal venous pulsations
- 2- Bilateral upgoing plantar responses
- 3- Normal ventricles on CT or MRI scan
- 4- Reduced visual acuity
- 5- Sixth cranial nerve palsy

Answer & Comments

Answer: 2- Bilateral upgoing plantar responses

BIH is typically associated with papilloedema, reduced venous pulsation and normal appearances of the magnetic resonance imaging (MRI).

A VIth nerve palsy is a recognised association.

Reflexes are preserved and plantars are flexor.

Extensor plantars suggest a alternative diagnosis.

[Q: 4199] OnExamination 2012 - Neurology

A 54-year-old female is admitted with progressive weakness following a trivial flu-like illness.

Which of the following would exclude Guillain-Barre syndrome (GBS) as the diagnosis?

- 1- Autonomic dysfunction

- 2- Elevated protein on CSF examination
- 3- Evidence of muscle wasting
- 4- Ophthalmoplegia
- 5- Sensory level below T1

Answer & Comments

Answer: 5- Sensory level below T1

GBS is a post-infectious acute polyneuritis typified by elevated cerebral spinal fluid (CSF) protein with few cells and often normal glucose.

There is a profound weakness associated with areflexia and peripheral sensory neuropathy.

Ophthalmoplegia is associated in particular with the Miller-Fisher variant.

However, a sensory level is not a feature and would suggest cervical myelopathy.

Muscle wasting is typical with prolonged illness.

Autonomic disease may also feature.

[Q: 4200] OnExamination 2012 - Neurology

A 21-year-old man recovered from the immediate effects of a head injury sustained in a motor cycle accident three months previously.

Which one of the following is the most likely delayed consequence of severe traumatic brain injury?

- 1- Episodic hypersomnia
- 2- Multiple obsessional symptoms
- 3- Outbursts of aggressive behaviour
- 4- Pathological jealousy
- 5- Persistent anxiety

Answer & Comments

Answer: 5- Persistent anxiety

The condition is post-concussion syndrome and although many of the symptoms given may be seen the commonest one (headache) has been left out.

The most common symptoms are headache and neck discomfort; changes in memory, concentration, and attention; dizziness; irritability, depression or anxiety; and sleep disturbance, among other symptoms.

There is:

Disturbance of thought

Poor concentration span and

Subjects are easily distracted.

Anxiety would seem the most common and therefore the most likely answer.

[Q: 4201] OnExamination 2012 - Neurology

A 65-year-old woman with 12 hour history of unsteady gait of sudden onset associated with vomiting and headache.

Following this she had increasing drowsiness.

What is the diagnosis?

- 1- Acute subdural haemorrhage
- 2- Cerebellar haemorrhage.
- 3- Frontal subdural empyema
- 4- Herpes simplex encephalitis.
- 5- Pituitary apoplexy.

Answer & Comments

Answer: 2- Cerebellar haemorrhage.

The history is very typical of cerebellar haemorrhage.

The drowsiness suggests the presence of hydrocephalus, a common complication of cerebellar haemorrhage.

[Q: 4202] OnExamination 2012 -
Neurology

A 60-year-old man awakens with painless loss of vision of his left eye.

Three years earlier he had suffered a similar episode involving the right eye. Visual loss in that eye has been stationary. He does not complain of any systemic symptoms.

What is the most likely diagnosis?

- 1- Acute angle-closure glaucoma
- 2- Arteritic ischaemic optic neuropathy
- 3- Compressive optic neuropathy
- 4- Nonarteritic ischaemic optic neuropathy
- 5- Optic neuritis

Answer & Comments

Answer: 4- Nonarteritic ischaemic optic neuropathy

Sudden onset of painless monocular visual loss in patients aged 50 or more is commonly due to ischaemic optic neuropathy.

Commonly the symptoms are first noticed upon awakening in the morning. The other eye may suffer a similar event within five years.

There are no systemic features (weight loss, lethargy, malaise, jaw claudication, scalp tenderness) to suggest arteritic ischaemic optic neuropathy (giant cell arteritis). In giant cell arteritis, the other eye is usually affected within four weeks.

Optic neuritis is unlikely in a man of this age who had painless loss of vision.

In older persons it is due to ischemia, which can be arteritic or non-arteritic. Non-arteritic anterior ischemic optic neuropathy based on cardiovascular risk factors essentially. Arteritic AION is concern with temporal arteritis which has a typical prodrome of jaw claudication, scalp tenderness and headaches

[Q: 4203] OnExamination 2012 -
Neurology

Which of the following is caused by a lesion of the parietal lobe?

- 1- Bitemporal hemianopia
- 2- Homonymous inferior quadrantanopia
- 3- Perseveration
- 4- Primitive reflexes
- 5- Wernicke's (receptive) aphasia

Answer & Comments

Answer: 2- Homonymous inferior quadrantanopia

Lesions of the frontal lobe include

Difficulties with task sequencing and executive skills

Expressive aphasia (receptive aphasia, a temporal lobe lesion)

Primitive reflexes

Perseveration (repeatedly asking the same question or performing the same task)

Anosmia

Changes in personality.

Lesions of the parietal lobe include

Apraxias

Neglect

Astereognosis (unable to recognise an object by feeling it)

Visual field defects (typically homonymous inferior quadrantanopia).

They may also cause acalculia (inability to perform mental arithmetic).

Lesions of the temporal lobe cause

Visual field defects (typically homonymous superior quadrantanopia)

Wernicke's (receptive) aphasia

Auditory agnosia

Memory impairment.

Occipital lobe lesions include

Cortical blindness (blindness due to damage to the visual cortex and may present as Anton syndrome where there is blindness but the patient is unaware or denies blindness)

Homonymous hemianopia

Visual agnosia (seeing but not perceiving objects - it is different to neglect since in agnosia the objects are seen and followed but cannot be named).

[Q: 4204] OnExamination 2012 - Neurology

A 76-year-old male presents with cognitive impairment and is diagnosed with dementia.

Which of the following is the most probable cause of the dementia?

- 1- Alzheimer's disease
- 2- Creutzfeldt-Jacob disease
- 3- Lewy body dementia
- 4- Pick's disease
- 5- Vascular dementia

Answer & Comments

Answer: 1- Alzheimer's disease

Dementia is a clinical state characterised by loss of function in multiple cognitive domains beyond what might be expected from normal aging.

Particularly affected areas may be memory, attention, language, and solving.

The most common form of dementia, Alzheimer's disease, accounts for 50-75% of all cases of dementia. The presenting symptom is usually forgetfulness for newly acquired information. As the disease

progresses there is disorientation and progressive cognitive decline with personality disruption.

Another 20-30% is due to blood vessel disease (multi-infarct dementia), and approximately 20% is dementia with Lewy Bodies. Frontotemporal dementia (Pick's disease) accounts for 5% of cases. The remaining cases result from a variety of less common disorders, including Creutzfeldt-Jacob disease, progressive supranuclear palsy, Huntingdon's disease and AIDS associated dementia.

[Q: 4205] OnExamination 2012 - Neurology

A 24-year-old female presents with vague frontal headaches and visual disturbance.

She has a past history of acne for which she is receiving treatment. Examination reveals her to be obese with a blood pressure of 110/70 mmHg. There is absence of the central retinal vein pulsation on fundoscopic examination.

Which of the following drugs account for these findings?

- 1- Ampicillin
- 2- Dianette
- 3- Erythromycin
- 4- Isotretinoin
- 5- Topical tetracycline

Answer & Comments

Answer: 2- Dianette

Dianette, like any oral contraceptive, may be associated with benign intracranial hypertension (BIH).

Topical tetracycline is not associated with BIH.

Rarely BIH has been associated with isotretinoin but usually in combination with a tetracycline.

[Q: 4206] OnExamination 2012 -
Neurology

A 31-year-old woman presents to the Emergency department following a witnessed first ever seizure. She is drowsy and confused postictally.

A CT brain shows petechial haemorrhages in the right hemisphere. An MRI shows cerebral venous sinus thrombosis.

Which of the following would be the best initial treatment?

- 1- Antibiotics
- 2- Aspirin
- 3- Heparin
- 4- Supportive management
- 5- Vitamin K

Answer & Comments

Answer: 3- Heparin

Venous sinus thrombosis is more common in young women.

It may present with headaches or symptoms of raised intracranial pressure.

It can cause seizures.

The underlying problem is a thrombosis and the petechial haemorrhages are caused by venous outflow blockage. It is therefore important that anticoagulation is started immediately to relieve the cause.

Heparin is the most appropriate anticoagulant to use in this circumstance.

A. Antibiotics are not the best answer. The underlying cause may be infection and it would be important to look for this and treat it. However, there is no sign of this in this case. It would be most important here to get on and treat the thrombosis.

B. Aspirin is not the best answer. The clot is venous therefore heparin is more appropriate.

C. Heparin is the correct answer.

D. Supportive management is not the best answer. The underlying thrombosis should be treated to relieve symptoms. The petechial haemorrhages should not put you off anticoagulating the patient.

E. Vitamin K is not the correct answer. The underlying problem is a clot which should be treated. Vitamin K can sometimes be used to treat coagulopathies in deficient patients; however that is not applicable here. The haemorrhages are secondary to the venous outflow blockage.

[Q: 4207] OnExamination 2012 -
Neurology

A 40-year-old male presents with abnormal movements.

On examination the patient has slow writhing movements of the arms and is unable to sit still in the chair without abnormal posturing. His father was reported to have had similar features at the age of 50 and died aged 60.

The pathophysiology of the disease described is similar to which of the following?

- 1- MELAS syndrome (mitochondrial encephalomyelopathy, lactic acidosis and stroke-like episodes)
- 2- Motor neuron disease
- 3- Myasthenia gravis
- 4- Myotonic dystrophy
- 5- Rheumatic fever

Answer & Comments

Answer: 4- Myotonic dystrophy

MELAS syndrome is a mitochondrial cytopathy caused by defects in the mitochondrial genome.

Motor neuron disease is a disorder of motor neurons the pathophysiology of which is

unclear but which is in some cases related to SOD-1 gene.

Myasthenia gravis is an autoimmune condition in which antibodies, typically anticholinesterase antibodies, interfere with neuromuscular transmission.

Rheumatic fever can present with choreiform movements (Sydenham's chorea) but it is caused by Group A Streptococci and antibody cross-reactivity.

Myotonic dystrophy and huntington's disease are both trinucleotide repeat expansions. DM is CTG and HD is CAG

[Q: 4208] OnExamination 2012 - Neurology

The Achilles reflex is supplied by which of the following?

- 1- L5
- 2- L5/S1
- 3- S1
- 4- S1/S2
- 5- S2

Answer & Comments

Answer: 3- S1

The L5 reflex is tested by tapping the medial hamstrings, but is typically cumbersome to do and not tested.

It is the asymmetry which is important as it is not necessarily present.

S2 reflex is part of the anocutaneous reflex or anal wink.

[Q: 4209] OnExamination 2012 - Neurology

A mother comes to your office concerned about her 2-year-old son.

She has noticed that he typically laughs inappropriately for no particular reason.

Shortly after an event he appears to be fidgeting. These events last only minutes and in between the events he acts normally. You suspect gelastic seizures.

From where do these typically arise?

- 1- Brainstem
- 2- Frontal lobes
- 3- Hypothalamus
- 4- Pineal gland
- 5- Temporal lobe

Answer & Comments

Answer: 3- Hypothalamus

Automatisms can be seen in temporal lobe seizures.

Frontal lobe involvement in neurodegenerative disease can cause emotional lability.

The pineal gland is involved in melatonin release.

If this were brainstem you would expect to see cranial nerve involvement which is not mentioned in the case.

[Q: 4210] OnExamination 2012 - Neurology

What is the likelihood of controlling seizures in a patient never previously on anti-epileptic medication with a single anti-convulsant agent?

- 1- 12%
- 2- 32%
- 3- 47%
- 4- 64%
- 5- 82%

Answer & Comments

Answer: 3- 47%

A study of patients with previously untreated epilepsy demonstrated that 47% achieved control of seizures with the use of their first single drug.

Fourteen per cent became seizure-free during treatment with a second or third drug.

An additional 3% became seizure-free with the use of two drugs simultaneously.

Reference:

Early identification of refractory epilepsy. NEJM 2000; 342(5):314-319

[Q: 4211] OnExamination 2012 - Neurology

A 70-year-old man presents with difficulty speaking.

He has a history of diabetes, hypertension, hypercholesterolaemia, chronic obstructive pulmonary disease. He is currently on aspirin, simvastatin, amlodipine and hydrochlorothiazide. On examination the patient is awake, his blood pressure is 150/70 mmHg. His pulse is irregularly irregular.

He has 4/5 strength in the right arm and leg and 5/5 strength on the left. When asked to point to the window he does this correctly. When told to raise his arms and place his hands out he is seen to have a pronator drift on the right. He is shown a pen and asked what it is. He is unable to identify it by name. He is asked to use it appropriately and begins to write on a piece of paper. When asked to repeat 'Today is a sunny day', he is able to do so.

What type of dysphasia is this consistent with?

- 1- Anomic aphasia
- 2- Broca's aphasia
- 3- Conduction aphasia
- 4- Transcortical motor aphasia
- 5- Transcortical sensory aphasia

Answer & Comments

Answer: 1- Anomic aphasia

In Broca's or non-fluent or expressive aphasia the patient is unable to name objects with poor comprehension and repetition. It localises to the Broca's area in the left posterior inferior frontal gyrus.

An injury to the anterior superior frontal lobe results in transcortical motor aphasia with good comprehension but poor verbal output with the exception of echolalia or repetition. Writing is usually also impaired. Repetition is also spared as the arcuate fasciculus is not involved.

Conduction aphasia has poor repetition and naming but intact comprehension and fluent verbal output.

It is different to the transcortical sensory and motor aphasia in that there is intact comprehension and fluency which are not seen in each of the transcortical aphasiae respectively.

[Q: 4212] OnExamination 2012 - Neurology

A 47-year-old man is admitted to the Emergency department after collapsing following a cricket match in his village. He was apparently hit on the head with the ball whilst batting, but got up afterwards.

During the following 30 minutes he became increasingly confused, drowsy and then unresponsive, slumped in a chair. On examination his BP is elevated at 180/110 mmHg, with a pulse of 58. His GCS is 6. He is intubated and ventilated.

Which of the following is the most appropriate treatment?

- 1- IV acetazolamide
- 2- IV alteplase
- 3- IV furosemide
- 4- IV heparin

5- IV mannitol

Answer & Comments

Answer: 5- IV mannitol

The history is classical for an extradural haemorrhage, and the clinical picture is consistent with raised intracranial pressure.

As such the initial treatment of choice is IV mannitol; it leads to reduced intracranial pressure and improves cerebral blood flow.

Hyperventilation is also considered to further reduce intracranial pressure whilst awaiting neurosurgical intervention.

[Q: 4213] OnExamination 2012 - Neurology

A 28-year-old man comes to the surgery complaining that he has begun waking from sleep in the early hours of the morning, unable to move. He is very distressed by this and is worried that he will become paralysed.

Additionally, he has begun to suffer from excessive sleepiness during the day and fell asleep once whilst out for dinner with a new girlfriend during the middle of the meal.

On examination his BP is 132/70 mmHg, pulse is 72 and regular. Neurological examination is entirely normal.

Investigations show

Haemoglobin 13.2 g/dl(13.5-18)

White cell count $6.0 \times 10^9/L$ (4-10)

Platelets $189 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (60-120)

Which of the following best describes the condition he suffers when he wakes from sleep?

1- Hypnagogic hallucinations

2- Restless legs syndrome

3- Sleep apnoea

4- Sleep paralysis

5- Sleep terrors

Answer & Comments

Answer: 4- Sleep paralysis

This patient has a history of sleep paralysis, excessive daytime somnolence and cataplexy. This triad of symptoms is suggestive of an underlying diagnosis of narcolepsy.

Diagnosis is a clinical one, supported by an overnight polysomnogram and multi sleep latency test.

Sleep hygiene is important in the management of the condition, with CNS stimulants being the main option with respect to pharmacological management.

Non-amphetamine based agents, such as modafinil, are the treatment of choice.

[Q: 4214] OnExamination 2012 - Neurology

A 32-year-old woman has presented to the emergency department for the third time with abdominal pain which typically lasts several days. The previous two occasions she has been discharged home without a firm diagnosis. Between episodes the patient is symptom free. She complains of feeling anxious.

She has recently re-started the combined oral contraceptive pill after completing her family.

On examination she is anxious and hypertensive at 155/98 mmHg with a pulse of 102. She has no rashes. Her abdomen is diffusely tender.

Investigations show

Haemoglobin 12.8 g/dl(13.5-18)

White cell count $8.1 \times 10^9/L$ (4-10)

Platelets $220 \times 10^9/L$ (150-400)

Sodium 135 mmol/l (134-143)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 100 µmol/l (60-120)

Which of the following is the most likely diagnosis?

- 1- Acute intermittent porphyria
- 2- Appendicitis
- 3- Depression
- 4- Porphyria cutanea tarda
- 5- Variegate porphyria

Answer & Comments

Answer: 1- Acute intermittent porphyria

Acute intermittent porphyria (AIP) is a rare disorder characterised by abdominal pain and neuropsychiatric symptoms which usually presents in the 20-40 age group. Rash is not a feature of AIP like other porphyrias. Hypertension and tachycardia are common examination findings.

The progesterone component of the combined oral contraceptive pill is known to precipitate porphyria attacks. Many other drugs have been described in association with an attack.

[Q: 4215] OnExamination 2012 - Neurology

A 59-year-old woman presents with polysymptomatology. On examination she has prominent fasciculations.

From which of the following conditions is she unlikely to suffer?

- 1- Cervical spondylosis
- 2- Motor neurone disease
- 3- Multiple sclerosis
- 4- Spinal muscular atrophy
- 5- Thyrotoxicosis

Answer & Comments

Answer: 3- Multiple sclerosis

Fasciculations suggest lower motor neurone disease. Fasciculations may be seen in otherwise normal individuals with no muscular weakness/atrophy. If pronounced and combined with muscle atrophy they usually signify motor neurone disease (MND).

They may also be seen in diseases that involve

Spinal cord grey matter

Lesions of anterior roots

Peripheral neuropathies.

They may also be seen with severe metabolic disturbance, dehydration, thyrotoxicosis, but not in demyelinating disease of the central nervous system.

[Q: 4216] OnExamination 2012 - Neurology

Which of the following anatomical considerations is correct?

- 1- Optic chiasm lesions characteristically produce a bitemporal hemianopia
- 2- The physiological blind spot is unaffected by papilloedema
- 3- In cortical blindness pupillary reactions are abnormal
- 4- Optic tract lesions produce an ipsilateral homonymous hemianopia
- 5- Cerebellar lesions cause horizontal nystagmus

Answer & Comments

Answer: 1- Optic chiasm lesions characteristically produce a bitemporal hemianopia

B. The physiological blind spot is enlarged in papilloedema as peripapillary photoreceptors are displaced.

- C. In cortical blindness, pupillary reflexes, eye movements and fundoscopy are all normal.
- D. Optic tract lesions produce an contralateral homonymous hemianopia.
- E. Horizontal nystagmus occurs in unilateral disease of the cerebral hemisphere, with the fast phase directed to the side of the lesion.

[Q: 4217] OnExamination 2012 - Neurology

A 29-year-old female presents with drooping of the left side of her face and an inability to close her left eye. She had a viral illness in the preceding week. There is no past medical history.

On examination, there is a left VIIth nerve palsy. The remaining cranial nerves are normal. Power, tone and reflexes are normal in the limbs.

What is the best course of treatment?

- 1- Intravenous immunoglobulin
- 2- No treatment
- 3- Oral Augmentin
- 4- Oral prednisolone
- 5- Oral valaciclovir and prednisolone

Answer & Comments

Answer: 4- Oral prednisolone

This is the classical history of a post-viral Bell's palsy.

There is some evidence to support a short course of steroids in the acute stages of the illness (NEJM 2007;357:1598-1607). This study suggests improved recovery of facial function with early treatment. No benefit was seen in aciclovir added to prednisolone in this study.

Oral valaciclovir has been evaluated with an RCT but consensus supports steroids (with some clinicians continuing to support the concomitant use of aciclovir).

You need to be confident that there are no features of Guillain-Barré (test reflexes), or brain stem vascular disease or space occupying lesion. The neurological examination of the cranial nerves thus needs to be completed with care.

[Q: 4218] OnExamination 2012 - Neurology

A 72-year-old male presents with weakness and reduced mobility.

On examination he has a slow gait with reduced arm swing and a tremor is noticed in the left arm.

Which of the following is the typical frequency of the rest tremor in Parkinson's disease?

- 1- 2 Hz
- 2- 4 Hz
- 3- 8 Hz
- 4- 10 Hz
- 5- 12 Hz

Answer & Comments

Answer: 2- 4 Hz

The tremor of Parkinson's disease is a rest tremor with low to moderate frequency 3 to 6 Hz.

Initially, the tremor is usually one-sided. As the disease progresses, the tremor becomes bilateral and increases in severity.

Although the classical tremor of Parkinson's disease is a rest tremor, over time an action tremor may develop. Furthermore, it may increase in severity with levodopa.

[Q: 4219] OnExamination 2012 - Neurology

A 55-year-old female presents with tremor of the hands which has been present for approximately five years.

She has a past medical history which includes anxiety and she receives salbutamol for asthma.

Examination revealed titubation and an upper limb postural tremor.

What is the most likely diagnosis?

- 1- Anxiety disorder
- 2- Benign essential tremor
- 3- Multiple sclerosis
- 4- Parkinson's disease
- 5- Salbutamol induced tremor

Answer & Comments

Answer: 2- Benign essential tremor

Anxiety and drugs (for example, salbutamol, sodium valproate, theophylline, amiodarone) are commonly associated with tremor of the limbs.

However, head tremor (titubation) is unusual. Essential tremor is the commonest cause of head tremor.

Parkinson's disease is associated with rest tremor but not titubation.

Multiple sclerosis is associated with titubation and intention tremor.

[Q: 4220] OnExamination 2012 - Neurology

A 40-year-old man has had decreased mentation with confusion as well as increasing incoordination and loss of movement in his right arm over the past six weeks.

An MRI scan shows 0.5 to 1.5 cm lesions in cerebral hemispheres in white matter and at the grey-white junction that suggest demyelination.

A stereotactic biopsy is performed, and immunohistochemical staining of the tissue reveals JC papovavirus in oligodendrocytes.

Which of the following laboratory test findings is most likely to be associated with these findings?

- 1- CD4 lymphocyte count of 90/microlitre
- 2- Haemoglobin A1c of 9.8%
- 3- HDL cholesterol of 0.7 mmol/L
- 4- Oligoclonal bands in CSF
- 5- Serum sodium of 110 mmol/L

Answer & Comments

Answer: 1- CD4 lymphocyte count of 90/microlitre

The findings are those of progressive multifocal leukoencephalopathy (PML), which is a condition that can develop in immunocompromised patients, such as those with AIDS.

PML is associated with papova (JC) virus infection.

[Q: 4221] OnExamination 2012 - Neurology

Which of the following is correct regarding herpes simplex encephalitis?

- 1- Is associated with a polymorphonuclear pleocytosis in the CSF
- 2- Produces a diffuse, evenly distributed inflammation of cerebral tissues
- 3- Produces a typical EEG pattern with lateralised periodic discharges at 2 Hz
- 4- Should be treated with acyclovir as soon as the diagnosis is confirmed by urgent CSF viral antibody titres
- 5- Shows a peak incidence in the autumn

Answer & Comments

Answer: 3- Produces a typical EEG pattern with lateralised periodic discharges at 2 Hz

This EEG pattern is seen but is not diagnostic.

Winter is the peak incidence.

A lymphocytosis is characteristic in the cerebrospinal fluid (CSF).

Temporal lobe location is typical not diffuse.

Immediate treatment is required on clinical suspicion - do not wait!

[Q: 4222] OnExamination 2012 - Neurology

A 50-year-old lady suffers with migraine. She smokes 20 cigarettes a day.

She has found that paracetamol 1 g was not always effective in relieving her pain.

Which of the following factors is the most likely to account for this problem?

- 1- Altered volume of distribution
- 2- Delayed gastric emptying
- 3- First pass metabolism
- 4- Hepatic enzyme induction
- 5- Reduced gut blood flow

Answer & Comments

Answer: 2- Delayed gastric emptying

Paracetamol absorption is reduced during migraine attacks and reduced absorption is associated with increased nausea.

There is evidence that delayed gastric emptying is to blame. (Tokola RA, Neuvonen PJ. Effect of migraine attacks on paracetamol absorption. Br J Clin Pharmacol 1984 Dec;18(6):867-71).

In fact the paracetamol absorption technique is used to study gastric emptying.

Enzyme induction with cigarette smoking does affect paracetamol metabolism. Its importance however, is in toxicity. Smokers would be classified as in a high risk for paracetamol overdose and are assessed using a different time - paracetamol level curve.

[Q: 4223] OnExamination 2012 - Neurology

A young teenager presents with fever and headache. He has received oral amoxicillin for three days.

Which of the following cerebrospinal fluid (CSF) findings would virtually exclude a partially treated bacterial meningitis?

- 1- A CSF glucose of 45% of blood glucose
- 2- A negative CSF culture
- 3- A negative Gram stain
- 4- A negative Kernig's sign
- 5- A white cell count of 3

Answer & Comments

Answer: 5- A white cell count of 3

The assessment of children with suspected bacterial meningitis who have already received antibiotic therapy from their GP is a common diagnostic problem.

Partial treatment may reduce the incidence of positive CSF Gram stains to less than 60%, and it also reduces the ability to grow the bacteria, particularly meningococcus.

CSF glucose, protein, neutrophils and bacterial antigen testing or polymerase chain reaction (PCR) should be completely unaffected. A normal white cell count would make the diagnosis very unlikely.

CSF glucose is usually > 65% of blood glucose.

[Q: 4224] OnExamination 2012 - Neurology

Which one of the following is associated with parkinsonian features?

- 1- Chronic carbon dioxide retention
- 2- Kernicterus
- 3- Lead poisoning
- 4- Mercury poisoning

5- Wilson's disease

Answer & Comments

Answer: 5- Wilson's disease

Poisons that can cause parkinsonism include:

Manganese

Carbon monoxide

Carbon disulfide

The cycad nut and

The illicit drug MPTP (methyl-phenyl tetrahydropyridine).

There are also other diseases of the brain that combine parkinsonism.

These include:

Wilson's disease

Huntington's disease

Shy-Drager syndrome

Striatonigral degeneration

Olivo-ponto-cerebellar degeneration

Cortical-basal ganglionic degeneration

Progressive supranuclear palsy

Diffuse Lewy body disease

Creutzfeldt-Jacob disease and even

Alzheimer's disease.

[Q: 4225] OnExamination 2012 - Neurology

A 25-year-old woman presents with a severe migraine.

Which of the following is not a recognised feature of migraine?

- 1- Bilateral fortification spectra
- 2- External ophthalmoplegia
- 3- Precipitation by oral contraceptives

4- Some symptoms improved by tricyclic antidepressants

5- Third nerve palsy

Answer & Comments

Answer: 2- External ophthalmoplegia

Fortification spectra (jagged lines resembling battlements) and teichopsia (flashes) are common. Tricyclics can be useful for nausea.

Third nerve palsy is seen in ophthalmoplegic migraine.

Chronic progressive external ophthalmoplegia usually develops in childhood and is associated with ptosis, fatigue and limitation to eye- movements in all directions.

The disorder is in the cytochromes.

[Q: 4226] OnExamination 2012 - Neurology

Which of the following statements regarding CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is correct?

- 1- Computerised tomography (CT) of the brain is diagnostic
- 2- Death usually occurs in infancy
- 3- It is associated with an abnormality of the X chromosome
- 4- It may present with migraine
- 5- The thalami are usually spared

Answer & Comments

Answer: 4- It may present with migraine

CADASIL is a diffuse disease of small arteries, predominantly in the brain.

It starts during mid adulthood and is characterised by:

Recurrent ischaemic events (transient or permanent)

Attacks of migraine with aura

Severe mood disorders

Sub-cortical dementia and

A wide spread leukoencephalopathy on magnetic resonance imaging (MRI).

CT brain is not diagnostic. Characteristic MRI changes include T2 weighted hyperintensity of the periventricular white matter.

A family history is almost always present, as it is an autosomal dominant condition, located to chromosome 19.

Infarcts are subcortical, and the thalami and basal ganglia are usually involved.

[Q: 4227] OnExamination 2012 - Neurology

A 39-year-old man is referred by his optician with a central scotoma found in his right eye during a routine eye test.

On examination of his cranial nerves he is poorly compliant and keeps laughing. He says he is unable to smell anything and that he can no longer read as well as he would like. On fundoscopy his left fundus is hyperaemic and oedematous. You are unable to obtain clear views of his right fundus.

Which of the following is the most likely diagnosis?

- 1- Drug abuse
- 2- Foster Kennedy's syndrome
- 3- Kallman's syndrome
- 4- Leber's hereditary optic neuropathy
- 5- Leigh syndrome

Answer & Comments

Answer: 2- Foster Kennedy's syndrome

Foster Kennedy's syndrome is a combination of optic atrophy and central scotoma, contralateral papilloedema and anosmia.

It is caused by optic and olfactory nerve compression and raised intracranial pressure. This is often secondary to a mass such as an olfactory groove meningioma.

Patients may also have other symptoms of raised intracranial pressure such as nausea and vomiting, and frontal symptoms such as emotional lability and memory loss.

A. This is not the best answer. Whilst drug abuse may account for his abnormal affect it would not cause the other symptoms.

B. .

C. This is not the correct answer. This is characterised by hypogonadism and anosmia.

D. This is not the correct answer. This is a mitochondrial disorder causing visual loss in young men but would not account for his other symptoms.

E. This is not the correct answer. This is a rare neurometabolic disorder affecting the central nervous system.

[Q: 4228] OnExamination 2012 - Neurology

A 55-year-old man has progressive weakness of his hands over a period of one year.

Examination reveals wasting of the muscles of the hands and forearms and fasciculation. There is hyperreflexia of his lower limbs and upgoing plantars. Sensation is normal.

Which of the following is the most likely diagnosis?

- 1- Alzheimer's disease
- 2- Motor neurone disease
- 3- Multiple cerebral infarcts
- 4- Multiple sclerosis
- 5- Syringomyelia

Answer & Comments

Answer: 2- Motor neurone disease

There is a mixture of lower motor neurone signs in the upper arms and upper motor neurone signs in the legs. Cerebrovascular disease and Alzheimer's disease are therefore unlikely.

The history is of gradual onset over one year which makes multiple sclerosis less likely since it is usually abrupt in the onset of symptoms.

Syringomyelia is unlikely since sensation is unaffected.

This leaves motor neurone disease particularly of the amyotrophic lateral sclerosis type.

[Q: 4229] OnExamination 2012 - Neurology

A 70-year-old man presents with difficulty speaking.

He has a history of diabetes, hypertension, hypercholesterolaemia, chronic obstructive pulmonary disease. He is currently on aspirin, simvastatin, amlodipine and hydrochlorothiazide.

On examination the patient is awake, his blood pressure is 150/70 mmHg. His pulse is irregularly irregular. He has 4/5 strength in the right arm and leg and 5/5 strength on the left. When asked to point to the window he does this correctly.

When told to raise his arms and place his hands out he is seen to have a pronator drift on the right. He is shown a pen and asked what it is. He is unable to identify it by name and appears frustrated: applying much effort to speak a sentence. He is asked to use it appropriately and begins to write on a piece of paper but no makes no legible words despite being a retired journalist. When asked to repeat 'Today is a sunny day', he is unable to do so.

With which of the following is this type of dysphasia consistent?

- 1- Broca's aphasia
- 2- Global aphasia
- 3- Transcortical motor aphasia
- 4- Transcortical sensory aphasia
- 5- Wernicke's aphasia

Answer & Comments

Answer: 1- Broca's aphasia

In Wernicke's or fluent or receptive aphasia the patient is able to form correct grammatical sentences but language content is incorrect. It localises to the dominant superior temporal gyrus. There is poor comprehension and repetition but verbal output is fluent.

In transcortical motor aphasia which localises to the anterior superior frontal lobe, the patient is able to repeat and have good comprehension but is unable to express themselves and have halting, effortful speech with intact repetition.

Transcortical sensory aphasia has intact repetition but the patient is unable to follow verbal commands with fluent grammatical speech.

Global aphasia results in an almost mute patient: there is poor verbal output, comprehension, repetition and understanding.

[Q: 4230] OnExamination 2012 - Neurology

Which of the following statements is true of acute compartment syndrome?

- 1- Loss of distal pulse is an early sign.
- 2- Only occurs following fractures.
- 3- Passive stretch of affected muscles exacerbates pain.
- 4- Rarely requires surgical intervention.

- 5- The presence of pain is unhelpful in diagnosis.

Answer & Comments

Answer: 3- Passive stretch of affected muscles exacerbates pain.

- A. Loss of peripheral pulses is a late sign indicating that the pressure within the compartment has exceeded arterial blood pressure.
- B. Compartment syndrome can occur in the absence of a fracture, for examples, crush injuries.
- C. Passive stretch of the muscles traversing the compartment increases pain.
- D. Treatment involves decompression of the affected compartment(s) including the skin.
- E. Pain is the earliest and most reliable symptom of the onset of compartment syndrome.

[Q: 4231] OnExamination 2012 - Neurology

A 18-year-old male presents with blurring of vision in his right eye.

Examination reveals visual acuity in the right eye of 6/18 and in the left eye 6/6.

Visual fields to confrontation reveal a right temporal visual field defect and partial loss of superior part of the temporal field of the left eye.

Where is the most likely position of the lesion responsible for this defect?

- 1- Occipital lobe
- 2- Optic chiasm
- 3- Optic nerve
- 4- Optic tract
- 5- Temporal lobe

Answer & Comments

Answer: 2- Optic chiasm

The most likely localisation of the lesion is around the optic chiasm spreading up the right optic nerve. The signs indicate a bitemporal visual field defect with involvement of the right optic nerve (decreased visual acuity).

Occipital lobe lesion causes a congruous homonymous hemianopia whereas an optic tract lesion causes an incongruous homonymous hemianopia. Temporal lobe lesion causes an upper homonymous quadrantanopia. Optic nerve lesions in isolation lead to unilateral visual signs.

Visual fields See also references.

[Q: 4232] OnExamination 2012 - Neurology

A 40-year-old civil servant attends the clinic stating that she has difficulty swallowing.

She gives a two month history of difficulty with solids which has progressed to difficulty tolerating liquids in the previous two weeks. She has noticed some weakness in her right arm which has affected her ability to lift certain objects like the kettle. Previously, she has enjoyed good health with no hearing loss or facial weakness. She describes no visual symptoms.

On examination, she has an absent gag reflex on the right, with reduced palatal movements. There is weakness on rotating the head to the left with flattening and weakness of elevation of the right shoulder. Eye movements, visual acuity, hearing and tongue movements are all normal.

Where is the likely site of the lesion?

- 1- Left cerebello-pontine angle
- 2- Left jugular foramen
- 3- Right cerebello-pontine angle
- 4- Right jugular foramen

5- Right pons

Answer & Comments

Answer: 4- Right jugular foramen

The clinical scenario is that of a right sided pathology affecting the IX, X and XI cranial nerves.

This produces the palatal weakness and the swallowing difficulties (IX/X), while the shoulder and sternocleidomastoid weakness are due to accessory nerve (XI) involvement.

The absence of hearing loss or facial weakness makes a cerebello-pontine angle lesion unlikely.

A lesion outside the skull may also involve the XII nerve (tongue).

The most likely site, therefore is the jugular foramen.

[Q: 4233] OnExamination 2012 - Neurology

A 70-year-old woman presented with episodic impairment of consciousness.

Which of the following is the most likely cause?

- 1- Alzheimer type dementia
- 2- Chronic subdural haematoma
- 3- Creutzfeldt-Jakob disease
- 4- Depressive stupor
- 5- Normal pressure hydrocephalus

Answer & Comments

Answer: 2- Chronic subdural haematoma

This is quite a grey question. The clinical scenario is very brief with no mention of any neurological signs so a logical deduction must be made.

Alzheimer's disease would be expected to have a continuous impairment of

consciousness in its advanced stages but could be episodic if there were variation in drugs therapy or concurrent illnesses.

Similarly normal pressure hydrocephalus, Creutzfeldt-Jakob and depression would present with dementia (or apparent dementia) but not fluctuant.

Of all those listed, subdural haematoma is classically associated with fluctuating level of consciousness. This would make it the most likely.

[Q: 4234] OnExamination 2012 - Neurology

Which of the following statements regarding central pontine myelinolysis is correct?

- 1- Consciousness is preserved characteristically.
- 2- MR imaging shows diagnostic features in the majority of patients.
- 3- The cause has been linked to over-rapid correction of hyponatraemic states.
- 4- The condition is confined to malnourished alcoholic patients.
- 5- The pathological changes are confined to the pons.

Answer & Comments

Answer: 3- The cause has been linked to over-rapid correction of hyponatraemic states.

Central pontine myelinolysis is a common consequence of over-rapid correction of hyponatraemia.

Pathological changes are not confined to the pons (despite the name of the condition).

Magnetic resonance imaging (MRI) usually shows changes within the pons, however the appearances are not diagnostic.

Consciousness is usually impaired.

It can occur in malnourished alcoholic patients (but it is not confined to them).

[Q: 4235] OnExamination 2012 - Neurology

Which of the following clinical manifestations suggests Guillain-Barré (GB) syndrome?

- 1- Asymmetrical involvement of distal muscles
- 2- Brisk tendon reflexes
- 3- Bulbar involvement in about 50% of cases
- 4- Normal cerebrospinal fluid (CSF) protein
- 5- Weakness beginning in the arms

Answer & Comments

Answer: 3- Bulbar involvement in about 50% of cases

GB is a post-infectious polyneuropathy causing demyelination in mainly motor but also sensory nerves.

It usually follows a non-specific viral infection. Campylobacter and Mycoplasma are recognised causes.

Weakness begins in the legs and progressively ascends to involve the trunk, upper limbs and finally the bulbar muscles (Landry's ascending paralysis).

Asymmetry is present in only 9% of patients, with symmetrical involvement being typical. Usually there is painless progression over days or weeks, but in cases of abrupt onset, there may be tenderness or muscle pain.

Bulbar involvement occurs in 50%, with a risk of aspiration and respiratory insufficiency can be problematic.

In the Miller Fisher syndrome there is external ophthalmoplegia, ataxia and areflexia.

In 20% of cases there is urinary incontinence or retention.

Clinical symptoms usually improve within two to three weeks, though a chronic relapsing form is recognised.

CSF protein is elevated to more than twice the upper limit of normal, with normal glucose and no pleocytosis. Bacterial cultures are negative and viral cultures rarely isolate anything.

The dissociation between a high CSF protein and a lack of cellular response in a person with an acute or subacute polyneuropathy is diagnostic of Guillain-Barre syndrome.

[Q: 4236] OnExamination 2012 - Neurology

A 21-year-old female with epilepsy is well controlled on sodium valproate 600 mg twice daily and had been taking oral contraceptives for three years.

She presented to her general practitioner 12 weeks pregnant.

Which of the following is correct?

- 1- An alternative anticonvulsant should be used in place of sodium valproate
- 2- Interaction of sodium valproate with the oral contraceptive increased the risk of pregnancy
- 3- She is at increased risk of anaemia in pregnancy
- 4- The dose of sodium valproate should be increased
- 5- There is an increased risk of a neural tube defect in her fetus

Answer & Comments

Answer: 5- There is an increased risk of a neural tube defect in her fetus

There is an increased risk of neural tube defects associated with anticonvulsants during pregnancy.

However, the risks associated with treatment are outweighed by the benefits in preventing seizures, so the drug should be continued.

The risks may be minimised through use of folate supplements.

Sodium valproate is not an enzyme inducer and would not speed up metabolism of the pill.

[Q: 4237] OnExamination 2012 - Neurology

An 18-year-old man presented with a history of a sudden onset of a frontal headache and photophobia. He had neck stiffness and a temperature of 38°C.

Which one of the following findings would suggest a diagnosis of subarachnoid haemorrhage rather than bacterial meningitis?

- 1- A blood neutrophil leucocytosis
- 2- A family history of polycystic renal disease
- 3- A fluctuating conscious level
- 4- A history of diabetes mellitus
- 5- A history of opiate abuse

Answer & Comments

Answer: 2- A family history of polycystic renal disease

Fluctuating level of consciousness can occur in both meningitis and subarachnoid haemorrhage (SAH).

Hypertension is a risk factor for SAH, but not diabetes.

Opiate abuse does not increase the risk for SAH.

Cerebral aneurysms are associated with polycystic kidney disease.

[Q: 4238] OnExamination 2012 - Neurology

A 43-year-old man presented with diplopia of six weeks duration.

On examination he had normal corrected visual acuity in each eye, restriction of adduction of the right eye and nystagmus in the left eye on left lateral gaze.

What is the most likely diagnosis?

- 1- Brainstem demyelination
- 2- Graves' ophthalmopathy
- 3- Internal carotid artery aneurysm
- 4- Lateral medullary syndrome
- 5- Steele-Richardson syndrome

Answer & Comments

Answer: 1- Brainstem demyelination

The features are suggestive of internuclear ophthalmoplegia which is due to a lesion at the medial longitudinal fasciculus and in this male the most likely explanation is multiple sclerosis (MS).

Other causes include brainstem infarction, syphilis and Lyme disease.

[Q: 4239] OnExamination 2012 - Neurology

A 70-year-old man presents with weight loss, lower limb weakness and dry mouth. He has been a heavy smoker.

On examination he looks cachectic; he has proximal lower limb weakness, areflexia (reflexes normalise with repetitive muscle contraction). There is no wasting or fasciculations. Sensory examination is normal.

Which of the following blood tests is the most likely to confirm the diagnosis?

- 1- Acetylcholine receptors
- 2- Anti GM1 antibody
- 3- Antinuclear antibody

- 4- Anti Ro/La antibodies
5- Voltage gated calcium channels antibodies

Answer & Comments

Answer: 5- Voltage gated calcium channels antibodies

The most likely diagnosis is Lambert-Eaton syndrome. It results when IgG autoantibodies blockade the voltage-gated calcium channels of peripheral cholinergic nerve territory.

Fifty per cent of the cases are associated with small cell lung carcinoma.

Proximal lower limb weakness is the most consistent neurological feature.

Ptosis and ophthalmoplegia are rare. Autonomic dysfunction is common (for example, dry mouth).

The reflexes are depressed or absent but normalise with repetitive muscle contraction.

[Q: 4240] OnExamination 2012 - Neurology

You are seeing a patient with rheumatoid arthritis in clinic.

You are keen to commence methotrexate. Before consenting to start the treatment your patient wants to know how often she is going to require blood tests.

What will you advise her?

- 1- FBC, LFT and U&E monthly, including baseline levels
- 2- FBC, coagulation screen, U&E and rheumatoid factor weekly, includes baseline levels
- 3- FBC, uric acid, folate levels, U&E and LFT at baseline and then weekly until on stable dose of methotrexate and then every two to three months.
- 4- FBC, LFT and U&E at baseline and then weekly until on stable dose of

methotrexate and then every two to three months

- 5- FBC, coagulation screen, LFT and ESR at baseline and then weekly until on stable dose of methotrexate and then every month.

Answer & Comments

Answer: 4- FBC, LFT and U&E at baseline and then weekly until on stable dose of methotrexate and then every two to three months

Methotrexate is a potent immunosuppressant and therefore has many potential side effects about which patients need to be counselled and the clinician aware.

There have been cases of fatal blood dyscrasias with bleeding and severe bone marrow suppression, putting patients at risk of severe infection. Liver cirrhosis and toxicity are other possible complications. These toxic effects can be reduced by the concurrent use of folic acid (except on the day of taking the methotrexate).

Methotrexate can also cause lung fibrosis.

Patients are therefore advised to seek medical advice if they have sore throat and illness, easy bruising or bleeding, shortness of breath, abdominal pain and vomiting or jaundice. It should be documented in patient notes that this advice has been given.

The current recommendation is to check baseline liver function, renal function and full blood count. This should then be repeated weekly until on a stable dose of methotrexate, when it can then be reduced to every two to three months if there has been no change in blood results.

Methotrexate should be stopped immediately if there is a clinically significant drop in white cell count or platelet count.

If there is derangement of LFTs it should also be stopped, but may be reintroduced after a couple of weeks if the LFTs normalise, but only under specialist advice.

[Q: 4241] OnExamination 2012 -
Neurology

A 67-year-old woman presents with severe back pain and urinary retention with overflow.

She says that her lower back has been aching for the past six weeks, but the pain has become significantly worse over the past 48 hours.

There is a medical history of hypertension, but nothing else of note. Her BP is 142/82 mmHg, pulse is 73 and regular.

She is unable to get off the couch due to distal lower limb weakness. Tone is increased bilaterally and her reflexes are increased. As you chat to her you notice fasciculation. There is perianal loss of sensation.

Which of the following is the most likely diagnosis?

- 1- Anterior spinal artery aneurysm
- 2- Anterior spinal artery thrombosis
- 3- Cauda equina syndrome
- 4- Conus medullaris syndrome
- 5- Sacroiliitis

Answer & Comments

Answer: 4- Conus medullaris syndrome

Conus medullaris syndrome presents with mixed upper and lower motor neurone signs. These include bilateral distal weakness with increased tone and hyper-reflexia, fasciculation. Sensory loss is most marked in the perianal region. It is much rarer than cauda equina syndrome.

Spinal cord infarction related to anterior spinal artery disease presents most frequently with sudden onset pain and loss of

power and sensation beginning in the thoracic region. The symptoms seen here have slowly built up over a few weeks and affect a more distal spinal cord distribution.

Sacroiliitis would not be associated with neurological deficit.

Cauda equina syndrome is associated with flaccid paralysis.

Conus Medullaris Syndrome
Cauda Equina Syndrome

Presentation
Sudden and bilateral
Gradual and may be unilateral leg signs initially

Reflexes
Knee jerks preserved, ankle jerks affected
Both knee and ankle jerks affected

Radicular pain
Less severe
More severe

Sensory
Numbness often localised to perianal area, dissociation

can occur, usually bilateral and symmetrical
Numbness often localised to the saddle area, may be

asymmetrical and unilateral, sensory loss often dermatomal

Motor
Symmetrical, hyperreflexic
disal paresis, less marked than

cauda equina, may be fasciculations
Areflexic paraplegic, may be asymmetric, more marked than

conus medullaris, fasciculations rare, atrophy more common

Impotence
Frequent
Often less marked

Sphincter

dysfunction
Urinary retention and atonic anal sphincter present early in

disease (can cause overflow urinary incontinence)
Urinary retention, usually presents later in course of disease

Low back pain
More marked
Less marked

[Q: 4242] OnExamination 2012 -
Neurology

A 67-year-old woman is referred to a neurologist complaining of difficulty getting out of her chair.

She is noted to have discrete erythematous papules over her metacarpophalangeal joints. Her creatine kinase (CK) is 4000.

What is your diagnosis?

- 1- Dermatomyositis
- 2- Myasthenia gravis
- 3- Myotonic dystrophy
- 4- Polymyositis
- 5- Polyneuropathy

Answer & Comments

Answer: 1- Dermatomyositis

Dermatomyositis and polymyositis are related conditions that present with proximal muscle weakness.

Dermatomyositis has cutaneous signs such as Gottron's papules, discrete erythematous papules over metacarpophalangeal joints, and a heliotrope rash.

Regarding the options:

A is correct as the high CK, proximal muscle weakness and skin changes suggest dermatomyositis.

B and C are incorrect as they would not produce a predominantly proximal neuropathy.

D is incorrect as it is not associated with skin changes.

E is incorrect as it produces a distal rather than proximal neuropathy.

[Q: 4243] OnExamination 2012 -
Neurology

A 20-year-old man presents to the Emergency

department after punching a window.

He has lacerated the medial aspect of his wrist, damaging the ulnar nerve.

What is he at risk of developing?

- 1- Claw hand
- 2- Inability to pinch paper between his thumb and index finger
- 3- Loss of sensation over the lateral three and a half fingers
- 4- Wasting of the second lumbrical muscle
- 5- Wasting of the thenar eminence

Answer & Comments

Answer: 1- Claw hand

Ulnar nerve damage at the wrist results in wasting of the intrinsic hand muscles (other than the lateral two lumbricals) and the hypothenar eminence. This produces the classic claw hand. It supplies sensation to the medial one and a half fingers.

The median nerve innervates the lateral two lumbricals and the thenar eminence (opponens pollicis, abductor pollicis and flexor pollicis brevis). It supplies sensation to the lateral one and a half fingers.

Damage to the motor branch, the anterior interosseous nerve results in inability to form and pinch grip, tip to tip, instead holding the paper between the pulp of the thumb and index finger.

[Q: 4244] OnExamination 2012 -
Neurology

A 45-year-old woman presented with a severe sudden onset headache, describing it as the worst headache she could imagine, but denying any head trauma.

On examination of her cranial nervous system she had a partial ptosis of her right eye, which was unable to look up or medially, and her

right pupil was dilated. Her only past medical history is polycystic kidney disease.

What is the most likely diagnosis?

- 1- Subarachnoid haemorrhage caused by a ruptured right sided posterior communicating artery aneurysm
- 2- Subarachnoid haemorrhage caused by a ruptured left sided posterior communicating artery aneurysm
- 3- Subarachnoid haemorrhage caused by a ruptured right sided anterior communicating artery aneurysm
- 4- Subarachnoid haemorrhage caused by a ruptured left sided anterior communicating artery aneurysm
- 5- First presentation of cluster headache

Answer & Comments

Answer: 1- Subarachnoid haemorrhage caused by a ruptured right sided posterior communicating artery aneurysm

Posterior communicating artery aneurysms can compress the third cranial nerve. If the aneurysm ruptures it can cause the classic picture of an ipsilateral painful third nerve palsy, with the eye down and out, ptosis, and pupil dilation.

Cerebral aneurysms may be associated with polycystic kidney disease.

Regarding the options:

A is correct. It is the ipsilateral posterior communicating artery aneurysm that is compressing the third nerve.

B is incorrect as posterior communicating artery aneurysms do not cause contralateral compressive symptoms.

C and D are incorrect as anterior communicating artery aneurysms do not compress the third nerve.

E is incorrect as the presentation is of a subarachnoid haemorrhage.

[Q: 4245] OnExamination 2012 - Neurology

Imaging changes in frontotemporal dementia (FTD) start initially in which parts of the brain?

- 1- Corpus callosum
- 2- Dorsolateral prefrontal cortex and anterior cingulate
- 3- Hippocampus, parahippocampus
- 4- Orbitofrontal cortex and anterior cingulate
- 5- Prefrontal cortex and anterior thalamic nucleus

Answer & Comments

Answer: 4- Orbitofrontal cortex and anterior cingulate

Damage to the hippocampus and parahippocampus results in memory problems and has early involvement in Alzheimer's disease.

The corpus callosum can be involved in multiple sclerosis where so-called Dawson's fingers can be seen.

Prefrontal cortex damage can result in disinhibition and problems with social interaction and judgement and has been implicated in schizophrenia.

[Q: 4246] OnExamination 2012 - Neurology

A 30-year-old male presents to the emergency room with headache. He describes that for the last week he has been having shooting pains on one side of the face with associated tearing of that eye.

He reports that for the past week he has been having similar pains intermittently. He last had an attack three months ago which lasted two weeks. He is concerned he has a brain tumour.

On examination the sclera is injected and the patient appears uncomfortable. There is no neck stiffness, fundoscopy is unremarkable. Eye movements are intact, visual fields are full to direct confrontation and there is no proptosis.

What is the most likely diagnosis?

- 1- Cluster headache
- 2- Complicated migraine
- 3- Migraine with aura
- 4- Tension headache
- 5- Trigeminal neuralgia

Answer & Comments

Answer: 1- Cluster headache

Migraine with aura does not present like this.

Trigeminal neuralgia is a definite differential however it usually is associated with face pain and does not involve the eye or come in clusters.

A complicated migraine typically has long tract findings of sensorimotor involvement of the limbs.

This presentation is not typical for tension headache.

[Q: 4247] OnExamination 2012 - Neurology

A 70-year-old man presents with difficulty speaking.

He has a history of diabetes, hypertension, hypercholesterolaemia, chronic obstructive pulmonary disease. He is currently on aspirin, simvastatin, amlodipine and hydrochlorothiazide.

On examination the patient is awake; his blood pressure is 150/70 mmHg. His pulse is irregularly irregular. He has 4/5 strength on the right arm and leg and 5/5 strength on the left.

When asked to point to the window he does this correctly. When told to raise his arms and place his hands out he is seen to have a pronator drift on the right. He is shown a pen and asked what it is. He is unable to identify it by name and appears frustrated, applying much effort to speak a sentence. He is asked to use it appropriately and begins to write on a piece of paper but no makes no legible words despite being a retired journalist. When asked to repeat 'Today is a sunny day', he is able to do so.

With what type of dysphasia is this consistent?

- 1- Broca's aphasia
- 2- Global aphasia
- 3- Transcortical motor aphasia
- 4- Transcortical sensory aphasia
- 5- Wernicke's aphasia

Answer & Comments

Answer: 3- Transcortical motor aphasia

In Broca's or non-fluent or expressive aphasia the patient is unable to name objects with poor comprehension and repetition. It localises to the Broca's area in the left posterior inferior frontal gyrus.

In Wernicke's or fluent or receptive aphasia the patient is able to form correct grammatical sentences but language content is incorrect. It localises to the dominant superior temporal gyrus. There is poor comprehension and repetition but verbal output is fluent.

Transcortical sensory aphasia is similar to transcortical motor aphasia in that there is good repetition but comprehension and fluency are poor.

Global aphasia results in an almost mute patient: there is poor verbal output, comprehension, repetition and understanding.

[Q: 4248] OnExamination 2012 -
Neurology

A 71-year-old man attends the memory clinic with his wife. She has noticed that he has become progressively more forgetful over the past few years and has begun to wander at night. Most recently he became lost whilst shopping in the local village and had to be brought home by the police. This caused his wife significant distress.

On examination in the clinic he has easily demonstrable short-term memory loss, with relative preservation of memory for events from his 40s. He also has visuospatial dysfunction.

His BP is 142/72 mmHg, his pulse is 78 and regular. There are no murmurs or bruits on auscultation.

Investigations showed

Haemoglobin 12.9 g/dl(13.5-17.7)

White cells $7.4 \times 10^9/L$ (4-11)

Platelets $193 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.6 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

CT head Mild cortical atrophy

Which of the following is the most likely diagnosis?

- 1- Alzheimer's dementia
- 2- Lewy body dementia
- 3- Multi-infarct dementia
- 4- Pick's disease
- 5- Shy-Drager syndrome

Answer & Comments

Answer: 1- Alzheimer's dementia

Given the relatively insidious onset of this gentleman's memory loss, now accompanied by visuospatial dysfunction, his unremarkable cardiovascular examination and relatively

normal CT head, Alzheimer's dementia seems the most likely diagnosis.

There are no features particularly consistent with emotional lability to indicate Pick's disease, and no features of Parkinson's, which would be consistent with Lewy body dementia or Shy-Drager syndrome.

Prescription of cholinergic agonists depends on a mini-mental state score of between 10 and 20 points.

[Q: 4249] OnExamination 2012 -
Neurology

A 70-year-old woman presents with acute back pain followed by weakness of dorsiflexion of her left foot.

Where would you expect the associated sensory loss?

- 1- Anterior thigh
- 2- Dorsum of foot
- 3- Perineum
- 4- Posterior calf
- 5- Sole of foot

Answer & Comments

Answer: 2- Dorsum of foot

The features suggest an L5 radiculopathy which would be associated with a loss of sensation in the dorsum of the foot and big toe.

[Q: 4250] OnExamination 2012 -
Neurology

Genetic anticipation occurs characteristically in all the following conditions, except which?

- 1- Fragile X syndrome
- 2- Huntington's disease
- 3- Marfan's syndrome
- 4- Myotonia dystrophica
- 5- Spinocerebellar ataxia type 1

Answer & Comments

Answer: 3- Marfan's syndrome

Anticipation means increased severity/earlier age of onset of disease with successive generations.

Other conditions with anticipation include

Spinocerebellar ataxia type 1

Dentatorubral-pallidoluysian atrophy.

[Q: 4251] OnExamination 2012 - Neurology

A 50-year-old man has drunk six units of alcohol a day for most of his adult life.

He has worsening symptoms of difficulty walking, headaches and urinary incontinence for the past ten months.

Of the following which is the most likely diagnosis?

- 1- Encephalopathy
- 2- Meningovascular syphilis
- 3- Normal pressure hydrocephalus
- 4- Syringomyelia
- 5- Wernicke-Korsakoff syndrome

Answer & Comments

Answer: 4- Syringomyelia

There is no suggestion of memory loss so normal pressure hydrocephalus and Wernicke-Korsakoff syndrome are less likely.

Encephalopathy is more likely to be associated with symptoms of drowsiness.

Although meningovascular syphilis can present in many different forms it is rather rare.

Syringomyelia is associated with headaches, motor and bladder symptoms and is the likely diagnosis. There is syrinx (fluid-filled cavitation) in the central spinal cord, usually

cervical. This can elongate and enlarge, causing compression of the corticospinal and spinothalamic tracts and anterior horn cells. Syringobulbia describes the situation when the syrinx extends into the brainstem. The commonest cause is impaired cerebrospinal fluid circulation, usually due to a Chiari malformation (also associated with arachnoiditis, meningeal carcinomatosis, space-occupying lesions or idiopathic). It is more common in men than women, and usually presents in the 20s and 30s although it can present later in life.

Sensory features are pain and temperature loss, classically in a shawl-like distribution and dysaesthesia. Light touch, vibration and position sense are affected later. Motor signs start as muscle wasting and weakness that begins in the hands, and progresses to affect the forearms and shoulders. Tendon reflexes are lost and there may be respiratory muscle involvement. Bladder, bowel and sexual dysfunction can develop, as can Horner's syndrome. Extension of the syrinx into the lumbar region can involve the legs.

Lumbar puncture should be avoided due to the risk of herniation. CT and MRI can be used to delineate the extent. Management involves physiotherapy, and neurosurgery to halt progression. Prognosis is variable, but early surgical involvement is beneficial.

In this scenario, the alcohol is a distractor.

[Q: 4252] OnExamination 2012 - Neurology

A 69-year-old male presents with cognitive impairment and a diagnosis of Alzheimer's disease is suspected.

What is the most appropriate test of short term memory?

- 1- Assessing orientation in time
- 2- Assessing serial 7s
- 3- Knowledge of the capital of the UK

- 4- Providing their home address
- 5- Recall of the doctor's name at the end of the consultation

Answer & Comments

Answer: 5- Recall of the doctor's name at the end of the consultation

Short term memory impairment is the commonest clinical presentation of Alzheimer's disease.

Usually patients are fully orientated in time, person and place. Long term memory is usually intact.

The best way to test short term memory is to ask the patient to recall new information in the next few minutes.

[Q: 4253] OnExamination 2012 - Neurology

A 36-year-old male patient with a long history of relapsing-remitting multiple sclerosis, develops double vision.

On examination of his eye movements abduction of either eye elicits nystagmus in that eye. Adduction is impaired in both eyes.

On MRI scanning, where will a new white matter lesion probably be evident?

- 1- Cerebellum
- 2- Cingulate gyrus
- 3- Medial longitudinal bundle
- 4- Optic chiasm
- 5- Parietal lobes

Answer & Comments

Answer: 3- Medial longitudinal bundle

Impairment of adduction in both eyes signifies an internuclear ophthalmoplegia. This is often accompanied by nystagmus of the abducting eye.

The area of the brain affected is the medial longitudinal bundle in the brain stem which connects the third and sixth nerve nuclei.

The main causes of internuclear ophthalmoplegia are

Multiple sclerosis tumour of the brainstem (glioma, for example)

Brainstem vascular lesions or

Wernicke's encephalopathy.

[Q: 4254] OnExamination 2012 - Neurology

A 55-year-old Caucasian man presented to hospital with fever, intermittent rigors, and worsening fatigue. He had returned from a business trip to West Africa six months previously.

What is the most likely diagnosis?

- 1- Brucellosis
- 2- Leishmaniasis
- 3- Plasmodium falciparum malaria
- 4- Plasmodium ovale malaria
- 5- Typhoid fever

Answer & Comments

Answer: 4- Plasmodium ovale malaria

The Duffy blood group on the red blood cells acts as a receptor for P. vivax. West Africans lack the Duffy blood group and therefore P. ovale replaces P. vivax in this region.

Both P. vivax and P. ovale have a liver hypnozoite stage which can cause repeated relapses.

P. falciparum typically presents within the first three months of return.

Visceral leishmaniasis is not endemic in West Africa.

Brucellosis is a zoonosis transmitted through contaminated and untreated milk and by

direct contact with infected animals. The incubation period of brucellosis is usually one to three weeks, but sometimes may be several months. It may have either a sudden or insidious onset and is accompanied by continued, intermittent, or irregular fever.

Typhoid fever presents within one to three weeks from return from an endemic area.

[Q: 4255] OnExamination 2012 - Neurology

A 15-year-old girl presented with a 12 hour history of fever and global headache.

On examination she was febrile (37.5°C). She was fully conscious. Mild neck stiffness was noted but there were no other neurological signs.

Cerebrospinal fluid analysis showed:

Cell count 200/mL (60% lymphocytes)

Protein 0.8 g/L (0.15-0.45)

Glucose 4.3 mmol/L (3.3-4.4)

Gram stain No organisms seen

What is the most likely diagnosis?

- 1- Bacterial meningitis
- 2- Cryptococcal meningitis
- 3- Lymphomatous meningitis
- 4- Tuberculous meningitis
- 5- Viral meningitis

Answer & Comments

Answer: 5- Viral meningitis

Enteroviruses and mumps are the commonest causes of viral meningitis.

Cerebrospinal fluid changes with bacterial meningitis typically include:

High protein

Low glucose and

Neutrophil pleocytosis.

Cryptococcal meningitis is an infection of severely immunocompromised individuals, especially advanced human immunodeficiency virus (HIV) infection.

Tuberculous meningitis is an insidious illness, presenting over weeks and months.

[Q: 4256] OnExamination 2012 - Neurology

A 39-year-old woman is found to have absent ankle jerks and gait disturbance.

Which of the following investigations is not indicated?

- 1- ANA
- 2- B12 levels
- 3- Cholestanol levels
- 4- Ferritin
- 5- VDRL

Answer & Comments

Answer: 4- Ferritin

Absent ankle jerks may occur in conditions associated with neuropathy (B12 deficiency, systemic lupus erythematosus [SLE], cerebrotendinous xanthomatosis) and dorsal root disease (tabes dorsalis).

Gait disturbance may occur for a variety of reasons:

Sensory ataxia in B12 deficiency and tabes dorsalis

Pyramidal signs in B12 deficiency and SLE

Cerebellar ataxia in cerebrotendinous xanthomatosis.

Cerebrotendinous xanthomatosis is an inherited condition, associated with accumulation of cholesterol in tissues including brain, peripheral nerve and tendons which produces a clinical picture of:

Early onset dementia

Gait ataxia

Loss of vibration sense

Cataracts

Large tendon xanthomata.

It is eminently treatable by the oral administration of chenodeoxycholic acid.

To clarify option 3, cholestanol is a derivative of cholesterol. In cerebrotendinous xanthomatosis there is a deficiency in sterol storage, and diagnosis is based on high serum (and tendon) cholestANOL. Serum cholesterol may be normal or low.

[Q: 4257] OnExamination 2012 - Neurology

A 17-year-old female is admitted with an oculogyric crisis.

Which of the following statements concerning this case is correct?

- 1- She is likely to have been prescribed olanzapine
- 2- She should be observed without treatment
- 3- She should be treated with parenteral procyclidine
- 4- She should receive procyclidine as long term prophylaxis
- 5- She is unlikely to have a recurrence

Answer & Comments

Answer: 3- She should be treated with parenteral procyclidine

Oculogyric crisis is an acute dystonic reaction of the face/eyes and is usually a consequence of typical neuroleptic drugs such as haloperidol and chlorpromazine but is unusual with newer agents such as olanzapine and clozapine.

The condition is often precipitated by re-introduction of the agent.

The condition should be treated with procyclidine (usually IV or IM) or benztropine.

Chronic treatment beyond a couple of days is not required.

[Q: 4258] OnExamination 2012 - Neurology

An 18-year-old woman sustains severe head injuries in a road traffic accident.

The following day her investigations show:

Sodium 160 mmol/l (137-144)

Potassium 3.7 mmol/l (3.5-4.9)

Chloride 120 mmol/l (95-107)

Urea 3.0 mmol/l (2.5-7.5)

Creatinine 90 µmol/l (60- 110)

Which one of the following statements is correct?

- 1- Rapid rehydration with 5% dextrose is indicated
- 2- She should be treated with sodium restriction
- 3- She has the syndrome of inappropriate antidiuretic hormone secretion (SIADH)
- 4- She will have a hyperchloraemic acidosis
- 5- Urine osmolality will be low

Answer & Comments

Answer: 5- Urine osmolality will be low

There is a marked hypernatraemia with elevated chloride but normal potassium and urea in a patient with severe head injuries.

The likely cause of this presentation is diabetes insipidus. Urine osmolality is therefore likely to be low.

You cannot say that she has a hyperchloraemic acidosis as you do not have her bicarbonate concentration but if you assume that the anion gap would be normal, that is 10-12, then this would suggest that the

bicarbonate is elevated, suggesting either a metabolic alkalosis or respiratory acidosis with compensation.

Although restoration of normal volaemia and osmolality is required, giving 5% dextrose may exacerbate any cerebral oedema and so correction should be gradual.

[Q: 4259] OnExamination 2012 - Neurology

An 80-year-old male presented with acute right-sided weakness.

Examination revealed minimal right facial weakness, impaired elevation of the right shoulder, with relatively preserved right hand strength. There was global weakness in the right leg which appeared to be maximal in the foot.

Which of the following arteries is most likely to have been affected?

- 1- Anterior cerebral artery
- 2- Lenticulostriate artery
- 3- Middle cerebral artery
- 4- Posterior cerebral artery
- 5- Posterior communicating artery

Answer & Comments

Answer: 1- Anterior cerebral artery

This is a tricky question, and purposely so.

The wording of the description could be due to middle or anterior artery circulation stroke but the challenge is to choose which is the more likely.

The case as described is the classic presentation of an anterior cerebral artery stroke as originally described in the literature. (Critchley M. The anterior cerebral artery and its syndromes. Brain 1930; 53:120-165.)

Unilateral occlusion (distal to ant. comm. origin) of anterior cerebral artery produces contralateral sensorimotor deficits mainly

involving the lower extremity with relative sparing of face and hands (think of the homunculus).

The lateral lenticulostriate artery is a branch of the middle cerebral artery. Occlusion causes damage to the internal capsule resulting in contralateral hemiparesis and sensory deficit. Speech may be affected (medial temporal lobe) as well as visual function (Meyer's loop: optic radiations affected).

Middle cerebral artery: Occlusion at the stem (proximal segment) results in:

Contralateral hemiplegia affecting face, arm, and leg (lesser)

Homonymous hemianopia - ipsilateral head/eye deviation

If on left: global aphasia.

Posterior cerebral artery: A variety of neurological syndromes including:

Pure hemisensory loss

Visual field loss- a variety

Visual agnosia

Disorders of reading (alexia, dyslexia) and more ...

[Q: 4260] OnExamination 2012 - Neurology

A 16-year-old girl presented with a three week history of headache and horizontal diplopia on far right lateral gaze. On two separate occasions she noted dimmed vision whilst bending forwards. Over the last year she had gained 12 kilograms in weight.

On examination, her weight was 95 kg, and height 162 cms.

Neurological examination revealed bilateral papilloedema and a partial right sixth cranial nerve palsy.

What is the most likely diagnosis?

- 1- Benign intracranial hypertension (BIH).
- 2- Multiple sclerosis.
- 3- Pituitary tumour
- 4- Superior sagittal vein thrombosis.
- 5- Thyroid eye disease.

Answer & Comments

Answer: 1- Benign intracranial hypertension (BIH).

This patient is markedly obese with a BMI of 36 and the history suggestive of BIH.

Vision may be affected with enlargement of the blind spot and the visual obscuration with movements that provoke a rise in intracranial pressure (ICP) (for example, bending) is typical of BIH.

Dysthyroid eye disease would not present like this and is more commonly associated with hyperthyroidism.

The papilloedema would argue against multiple sclerosis (MS).

A bitemporal hemianopia or a visual field defect would be expected with a pituitary tumour.

Venous sinus thrombosis is a possibility but would be expected to produce deteriorating symptoms.

[Q: 4261] OnExamination 2012 - Neurology

Which visual field defect is most likely to occur with multiple sclerosis?

- 1- Bitemporal hemianopia
- 2- Central scotoma
- 3- Homonymous hemianopia
- 4- Increased blind spot
- 5- Tunnel vision

Answer & Comments

Answer: 2- Central scotoma

Central scotoma is likely with retrobulbar neuritis and optic atrophy.

Tunnel vision occurs in glaucoma, retinitis pigmentosa and retinal panphotocoagulation.

Increased blind spot occurs with papilloedema, which may lead to optic atrophy.

Optic chiasma compression causes bitemporal hemiopia.

[Q: 4262] OnExamination 2012 - Neurology

Which of the following features are not compatible with the diagnosis of motor neurone disease (MND)?

- 1- Dementia
- 2- Dysphagia
- 3- Muscle cramps
- 4- Neck weakness
- 5- Optic atrophy

Answer & Comments

Answer: 5- Optic atrophy

Ten per cent of patients with MND have dementia (frontotemporal).

Optic atrophy is not a feature of MND.

Other features not compatible with the diagnosis are sensory impairment and bladder dysfunction.

[Q: 4263] OnExamination 2012 - Neurology

A 25-year-old old woman presents with two hours of a unilateral temporal headache increasing in severity. The pain is of a throbbing character and is exacerbated by light.

There are no abnormal signs on examination.

What is the diagnosis?

- 1- Acute subarachnoid haemorrhage.
- 2- Cluster headache.
- 3- Intracranial tumour.
- 4- Migraine.
- 5- Tension headaches.

Answer & Comments

Answer: 4- Migraine.

Migraine is the commonest cause of headache in young patients.

Photophobia, unilateral presentation and normal examination will be consistent with migraine.

[Q: 4264] OnExamination 2012 - Neurology

A 62-year-old man presented with difficulty in walking. He had a past history of diabetes mellitus and cervical spondylosis, which had required surgical decompression eight years previously. He drank 40 units of alcohol weekly.

On examination there was fasciculation, wasting and weakness in the left deltoid and biceps, with weakness in the shoulder girdle muscles bilaterally.

There was fasciculation in the glutei and quadriceps bilaterally, weakness of hip flexion and foot dorsiflexion, brisk reflexes in upper and lower limbs, and extensor plantar responses. There was no sensory impairment.

What is the diagnosis?

- 1- Alcoholic myopathy
- 2- Diabetic amyotrophy
- 3- Motor neurone disease
- 4- Recurrent cervical cord compression
- 5- Syringomyelia

Answer & Comments

Answer: 3- Motor neurone disease

There are signs of lower (wasting, fasciculations) and upper (brisk reflexes, extensor plantar response) motor neuron involvement in the presence of normal sensation.

Motor neuron disease is the most common cause of such presentation.

Alcoholic myopathy and diabetic amyotrophy do not share upper motor neuron signs.

Syringomyelia presents with sensory symptoms and signs (spinothalamic).

You expect sensory involvement with cervical cord compression.

[Q: 4265] OnExamination 2012 - Neurology

A female patient aged 30 has a five year history of difficulty getting upstairs and out of a low chair and mild upper limb weakness but no pain. There is no family history.

She presented with severe type 2 respiratory failure. EMG showed evidence of myopathy.

Which is the most likely diagnosis?

- 1- Acid maltase deficiency
- 2- Inclusion body myositis
- 3- Lambert-Eaton myasthenic syndrome
- 4- Miller-Fisher syndrome
- 5- Polymyositis

Answer & Comments

Answer: 1- Acid maltase deficiency

Acid maltase deficiency typically presents with insidious onset of proximal myopathy and early respiratory muscle weakness.

Respiratory failure in inflammatory myopathies (polymyositis, dermatomyositis, inclusion body myositis) and limb girdle

muscular dystrophy are rare. Muscle biopsy shows vacuolation in muscle fibres.

Miller-Fisher syndrome, a variant of Guillain-Barré syndrome, is characterised by ophthalmoplegia, ataxia and areflexia.

Lambert-Eaton myasthenic syndrome, often a paraneoplastic phenomenon, is associated with hyporeflexia which returns after exercise, autonomic symptoms and fatigability.

[Q: 4266] OnExamination 2012 - Neurology

A broad-based ataxic gait occurs characteristically with which of the following?

- 1- Basal ganglia lesion
- 2- Cerebellar vermis lesion
- 3- Phenytoin toxicity
- 4- Proximal myopathy
- 5- Right-sided cerebral infarction

Answer & Comments

Answer: 3- Phenytoin toxicity

Broad based gait is associated with cerebellar syndrome. However, lesions of cerebellar vermis cause truncal ataxia and tendency to fall backwards.

Basal ganglia disease causes extrapyramidal signs with parkinsonism (festinant gait, marche à petits pas).

Proximal myopathy causes a waddling gait.

Right-sided cerebral infarction is associated with a hemiplegic gait.

[Q: 4267] OnExamination 2012 - Neurology

Causes of a small pupil include which of the following?

- 1- Carbon monoxide poisoning

2- Ethylene glycol poisoning

3- Holmes-Adie pupil

4- Pontine haemorrhage

5- Third nerve palsy

Answer & Comments

Answer: 4- Pontine haemorrhage

Causes of small pupils include:

Horner's syndrome

Old age

Pontine haemorrhage

Argyll Robertson pupil

Drugs and poisons (opiates, organophosphates).

Causes of dilated pupils include:

Holmes-Adie (myotonic) pupil

Third nerve palsy

Drugs and poisons (atropine, cobalt [CO], ethylene glycol).

[Q: 4268] OnExamination 2012 - Neurology

A previously well 27-year-old woman presents with a history of transient ischaemic attack affecting her right side and speech.

She had returned to the United Kingdom from a holiday in New Zealand two days previously.

On examination there was nothing abnormal to find. An ECG, chest x ray, CT brain scan and routine haematology and biochemistry were all normal.

What is the most likely underlying abnormality?

- 1- Atrial myxoma
- 2- Carotid artery stenosis
- 3- Embolus from paroxysmal atrial fibrillation
- 4- Patent foramen ovale

5- Subarachnoid haemorrhage

Answer & Comments

Answer: 4- Patent foramen ovale

This is a typical cause of stroke in a young person due to prolonged immobility.

Deep vein thrombosis with patent foramen ovale will cause paradoxical embolism and stroke.

[Q: 4269] OnExamination 2012 - Neurology

A 72-year-old male presented with a quadrantic hemianopia.

Which of the following conditions is most likely to cause such a presentation?

- 1- A lesion of the occipital cortex
- 2- A lesion of the optic chiasma
- 3- Bilateral diabetic retinopathy
- 4- Chloroquine poisoning
- 5- Tobacco amblyopia

Answer & Comments

Answer: 1- A lesion of the occipital cortex

Unilateral occipital lobe lesions (left or right) cause contralateral hemianopsia or quadrantanopsia, visual agnosia, visual illusions and elementary visual hallucinations.

Left occipital lobe lesions cause these symptoms and alexia and colour agnosia.

Right occipital lobe lesions cause impaired visual orientation and topographical memory in addition.

Bioccipital lesions are rare, but cause cortical blindness, altitudinal hemianopsia, impaired colour perception, Anton syndrome and prosopagnosia.

A lesion of the optic chiasm would cause a bitemporal hemianopia.

Diabetic retinopathy can rarely cause an 'apparent quadrantic hemianopia' because the distribution of the retinal changes may just correspond to quadrantic hemianopia - but this is not the most likely.

Tobacco amblyopia causes symmetric central or centrocaecal scotomas.

Chloroquine poisoning causes symmetric bilateral scotomas.

[Q: 4270] OnExamination 2012 - Neurology

Which of the following is a form of generalised seizure?

- 1- Automatisms
- 2- Aversive seizures
- 3- Benign rolandic epilepsy
- 4- Epilepsia partialis continua
- 5- Lennox-Gastaut syndrome

Answer & Comments

Answer: 5- Lennox-Gastaut syndrome

Seizures may be classified as:

A. Partial

Simple partial (consciousness retained), motor, sensory, autonomic, psychic

Complex partial (consciousness impaired)

Simple partial followed by impaired consciousness, or consciousness impaired at onset

Partial seizures with secondary generalisation

B. Generalised seizures

Absences (typical or atypical)

Generalised tonic clonic

Tonic

Clonic

Myoclonic

Atonic

Infantile spasms

C. Unclassified averse seizures are a form of simple partial seizure, consisting of head turning and conjugate eye movements.

Rasmussen's encephalitis is a subacute inflammatory encephalitis, and is one cause of epilepsia partialis continua.

Complex partial seizures often contain automatisms which may be elementary (including lip smacking, chewing, swallowing or salivation), or automatic behaviour (semi-purposive unco-ordinated or unplanned gestures including picking and pulling at clothing).

Rolandic epilepsy is a benign partial epilepsy associated with centro-temporal spikes. There is an excellent prognosis.

[Q: 4271] OnExamination 2012 - Neurology

Which of the following forms of encephalitis is caused by a neuroimmunological response?

- 1- Cytomegalovirus
- 2- Enteroviruses
- 3- Herpes simplex
- 4- HIV infection
- 5- Measles

Answer & Comments

Answer: 5- Measles

Encephalitis may be caused by:

Direct invasion by a neurotoxic virus (encephalitis)

Post-infectious encephalopathy: delayed brain swelling because of an immunological response to the antigen

Slow virus infection, for example, human immunodeficiency virus [HIV] or subacute sclerosing panencephalitis [SSPE].

Direct infection is most commonly caused by enteroviruses, herpes simplex virus (HSV) 1 and 2, varicella, cytomegalovirus (CMV), and Epstein-Barr virus (EBV).

It is also occasionally caused by respiratory viruses, human herpes virus 6 (HHV6), rubella or mumps.

A post-infectious illness may also be caused by measles or varicella zoster (cerebellar ataxia).

[Q: 4272] OnExamination 2012 - Neurology

In considering the management of convulsions select the correct statement from the list below.

- 1- Hypoglycaemia should always be considered.
- 2- If the fit lasts longer than five minutes, then PR diazepam should be given.
- 3- Paraldehyde is best given intramuscularly.
- 4- Phenobarbitone is a useful therapy in school age children.
- 5- When associated with fever, antibiotics should always be given to cover the possibility of meningitis.

Answer & Comments

Answer: 1- Hypoglycaemia should always be considered.

Status epilepticus is traditionally defined as continuous convulsion lasting longer than 30 minutes, or the occurrence of serial convulsions between which there is no return of consciousness.

It may be generalised (tonic clonic, absent) or partial (simple, complex, or with secondary

generalisation). Generalised tonic clonic seizures predominate.

There are three major sub-types:

Prolonged febrile seizures.

Idiopathic status epilepticus (no underlying central nervous system [CNS] lesion or insult).

Symptomatic (longstanding neurological disorder or metabolic abnormality).

The most common cause in a child less than 3 years is a prolonged febrile seizure. Sleep deprivation and drug withdrawal can also precipitate it.

The relationship between neurological outcome and duration of status epilepticus is unknown in children and adults. In the animal model, 60 minutes of constant seizure activity is associated with pathological changes, even when metabolic homeostasis is maintained.

Cell death thus results in increased metabolic demands from continually discharging neurones. Vulnerable areas include the hippocampus, the mid to low cerebellum, middle cortical areas, and thalamus.

Approximately 20 minutes of status epilepticus produces regional oxygen sufficiency deficiency promoting cell damage and necrosis. This is, therefore, used as the threshold in children.

Initial management begins with ABC.

Remember DEFG (Don't Ever Forget Glucose): Hypoglycaemia should be excluded as it is easily and rapidly treatable (if present 3-5 ml/kg of 10% dextrose is given by IV infusion), and blood obtained for full blood count, electrolytes including calcium and magnesium, glucose, creatinine, anticonvulsant levels. Blood and urine may be obtained for toxicology. Arterial blood gases should be done, and consideration given to lumbar puncture.

First line anticonvulsant therapy would be lorazepam/diazepam given IV if possible. If seizures persist then phenytoin may be given as a loading dose followed by an infusion.

Phenobarbitone may be used as first line in infants. Paraldehyde can be given as a dilute solution intravenously, or administered rectally or IM. The latter two routes can produce tissue damage and sloughing, so these should be reserved for exceptional circumstances.

[Q: 4273] OnExamination 2012 - Neurology

Which is true of herpes simplex encephalitis?

- 1- Brain MRI is characteristically normal
- 2- Fits are uncommon
- 3- Genital herpes is usually present
- 4- Temporal lobe involvement is common
- 5- Viral identification using polymerase chain reaction (PCR) on CSF is non-specific

Answer & Comments

Answer: 4- Temporal lobe involvement is common

Herpes simplex encephalitis (HSE) is associated with high signal in one or both temporal lobes (limbic encephalitis).

Seizures are commonly present in HSE.

Herpes simplex virus type 1 is the causative virus (not type 2 which is associated with genital herpes).

PCR for herpes simplex virus on cerebral spinal fluid (CSF) is a highly specific test.

[Q: 4274] OnExamination 2012 - Neurology

A 62-year-old male is noted to have a broad-based ataxic gait.

This is characteristic of which of the following?

- 1- A basal ganglia lesion
- 2- Cerebellar vermis lesion
- 3- Osteomalacia
- 4- Phenytoin toxicity
- 5- Right-sided cerebral infarction

Answer & Comments

Answer: 4- Phenytoin toxicity

Broad-based gait is associated with cerebellar syndrome.

However, lesions of cerebellar vermis cause truncal ataxia and tendency to fall backwards.

Right-sided cerebral infarction is associated with a hemiplegic gait.

Basal ganglia disease causes extrapyramidal signs with parkinsonism (festinant gait, marche à petit pas).

Proximal myopathy causes a waddling gait.

[Q: 4275] OnExamination 2012 - Neurology

A 60-year-old male with a history of diabetes, hypertension and hypercholesterolaemia presents with dizziness.

He reports that he woke up this morning and attempted to get out of bed but felt dizzy. He vomited and was unable to get out of bed to go to the bathroom. His wife was concerned as this had never happened before and called for the ambulance.

On arrival at the emergency room his blood pressure was 180/70 mmHg, pulse was regular at 60 beats per minute and he was afebrile. Blood sugar was within normal limits.

On neurological examination his visual fields were full, and fundoscopy was notable for grade 2 hypertensive retinopathy. He had left

jerk nystagmus on looking to the left and left jerk nystagmus on looking to the right. He was able to perform finger to nose and heel to shin in the bed.

On standing the patient felt dizzy. His blood pressure was 170/80 mmHg after three minutes standing. He refused to walk for fear of falling. The rest of his examination was unremarkable.

What is the leading diagnosis at this time?

- 1- Benign paroxysmal positional vertigo
- 2- Cerebrovascular accident
- 3- Hypertensive emergency
- 4- Labyrinthitis
- 5- Orthostatic hypotension

Answer & Comments

Answer: 1- Benign paroxysmal positional vertigo

Although there is no dysmetria a patient can have vertigo in isolation from a stroke.

Typically however the patient has direction changing nystagmus. You would be more reassured if the patient were able to walk. A trial of meclizine prior to walking may help.

A cerebrovascular accident should be considered and an MRI obtained of the brain.

The patient is not orthostatic on examination by definition.

Labyrinthitis typically has associated tinnitus and a history of infection or head trauma.

[Q: 4276] OnExamination 2012 - Neurology

A 27-year-old man presents with three months of difficulty walking.

Examination reveals motor weakness of left leg in a pyramidal distribution with increase in tone. There is impaired pinprick sensation of right leg extending into the groin.

What is the cause of these signs?

- 1- A central cauda equina lesion.
- 2- A cervical spinal cord lesion.
- 3- A foramen magnum lesion.
- 4- A left sided thoracic spinal cord lesion.
- 5- Bilateral cerebral hemisphere lesions.

Answer & Comments

Answer: 4- A left sided thoracic spinal cord lesion.

The history suggests Brown-Sequard syndrome produced by a hemisection of the spinal cord.

The clinical presentation is that of ipsilateral weakness and a loss of position and vibration below the lesion with contralateral loss of pain and temperature.

[Q: 4277] OnExamination 2012 - Neurology

A 75-year-old man is brought to see you by his wife. She is no longer able to manage his urinary incontinence.

He was diagnosed with Parkinson's disease by his GP a few years ago when he became slow and shuffling and used to struggle to get to the toilet in time. She says he 'lost a lot of the warning' from his bladder and would sometimes be incontinent. However, his wife says he now no longer seems to care whether he is being incontinent of urine or not. She admits that he has been 'forgetful' for a few years but that this is also getting much worse.

What is the most likely diagnosis?

- 1- Alzheimer's dementia
- 2- Lewy body dementia
- 3- Normal pressure hydrocephalus
- 4- Obstructive uropathy
- 5- Parkinson's plus syndrome

Answer & Comments

Answer: 3- Normal pressure hydrocephalus

Normal pressure hydrocephalus causes the triad of dementia, gait abnormality and urinary incontinence.

It is a cause of reversible dementia as symptoms may resolve with a shunt, so is an important diagnosis not to miss.

The gait can often be confused with that of a Parkinson's patient.

Urinary problems often begin as urgency and frequency and may progress to frontal lobe incontinence (patients are indifferent to their incontinence).

Sometimes diagnosing conditions, particularly dementias, may be difficult in the early stages. Always be ready to consider reviewing a previous diagnosis (such as this patient's previous diagnosis of Parkinson's disease) in light of new symptoms.

A. Alzheimer's dementia is not the answer. This initially causes forgetfulness, patients then undergo progressive cognitive decline with disintegration of personality. Urinary incontinence and gait disturbance are not typical features.

B. Lewy body dementia is not the answer. Patients with this problem typically complain of visual hallucinations and fluctuating cognition. They usually have a degree of parkinsonism, but urinary incontinence is not typically prominent.

C. Normal pressure hydrocephalus is the correct answer (see above).

D. Obstructive uropathy is not the correct answer. This may cause overflow incontinence of the bladder and confusion, particularly in patients with already impaired cognition. However, it would not explain the patient's indifference to his incontinence.

E. Parkinson's plus syndrome is not the correct answer. This is a group of neurodegenerative disorders with classical parkinsonian signs and some additional features. However, this history does not fit well with any of these conditions.

[Q: 4278] OnExamination 2012 - Neurology

A 25-year-old woman presents with new double vision.

On examination she experiences horizontal diplopia on looking to her far right. Covering her left eye only obscures the innermost image. Covering her right eye only obscures the outermost image. In the neutral position her right eye is deviated medially. She has no problem on looking to the far left.

Her neurological examination is otherwise normal.

What is the most likely problem?

- 1- Concomitant right esotropia
- 2- Left sided IVth nerve palsy
- 3- Left sided VIth nerve palsy
- 4- Medial longitudinal fasciculus lesion
- 5- Right sided VIth nerve palsy

Answer & Comments

Answer: 5- Right sided VIth nerve palsy

The VIth nerve is motor to the lateral rectus muscle.

It is responsible for abduction of the ipsilateral eye.

In the neutral position the affected eye is deviated medially due to unopposed action of the medial rectus.

In patients with diplopia the 'cover test' can be used to determine the eye that has the problem. On covering the affected eye the outermost image disappears.

After finding a VIth nerve palsy the cause should always be looked for, it is not a diagnosis in itself.

Due to the long course and anatomy of the VIth nerve it can be damaged in any condition causing raised intracranial pressure. It can therefore be a 'false localising sign'.

Regarding the options:

Concomitant right esotropia is not the answer. An esotropia is a squint where one or both eyes turn inwards. This may alternate between the eyes or may be a problem in just one eye. A concomitant esotropia is a squint where the degree by which the eye turns inwards does not vary in any direction of gaze (as opposed to an incomitant esotropia where the direction of gaze does affect the size or presence of deviation). Concomitant esotropias usually begin early in childhood. The patient has diplopia in all directions of gaze if vision is normal in both eyes.

Left sided IVth nerve palsy is not the answer. The IVth nerve controls the superior oblique muscle. Lesions of it typically cause a vertical diplopia, usually noticed on going downstairs or reading.

Left sided VIth nerve palsy is not the answer. This would cause a horizontal diplopia but it would be on far left gaze. The outermost image would disappear with the cover test over the left eye if it was affected.

A medial longitudinal fasciculus lesion is not the answer. This connects the IIIrd and VIth cranial nerve nuclei in the pons and coordinates conjugate horizontal eye movements. Its lesions typically cause internuclear ophthalmoplegia. There will be impaired adduction on the side of the lesion with nystagmus of the contralateral eye. In the neutral position the eyes appear normal.

Right VIth nerve palsy is the correct answer (see above).

[Q: 4279] OnExamination 2012 -
Neurology

What is the most common finding in Cheyne-Stokes breathing?

- 1- Heart failure
- 2- Liver failure
- 3- Pilocytic astrocytoma
- 4- Renal failure
- 5- Stroke

Answer & Comments

Answer: 1- Heart failure

Stroke and metabolic dysfunction can also result in Cheyne-Stokes apnoea but are not as common as heart failure.

Cheyne-Stokes is a type of central sleep apnoea in which there is loss of chest and abdominal movements and crescendo-decrescendo breathing in a repetitive fashion.

Treatments include diuretics and non-invasive ventilation.

[Q: 4280] OnExamination 2012 -
Neurology

A 70-year-old man presents with difficulty speaking.

He has a history of diabetes, hypertension, hypercholesterolaemia, chronic obstructive pulmonary disease. He is currently on aspirin, simvastatin, amlodipine and hydrochlorothiazide. On examination the patient is awake, his blood pressure is 150/70 mmHg. His pulse is irregularly irregular.

He has 4/5 strength in the right arm and leg and 5/5 strength on the left. When asked to point to the window he does this correctly. When told to raise his arms and place his hands out he is seen to have a pronator drift on the right. He is shown a pen and asked what it is. He responds fluently but makes some paraphasic errors. He is asked to use it

appropriately and begins to write on a piece of paper. When asked to repeat 'Today is a sunny day', he is unable to do so.

Which of the following terms best describes these signs?

- 1- Anomic aphasia
- 2- Broca's aphasia
- 3- Conduction aphasia
- 4- Transcortical motor aphasia
- 5- Transcortical sensory aphasia

Answer & Comments

Answer: 3- Conduction aphasia

In Broca's or non-fluent or expressive aphasia the patient is unable to name objects with poor comprehension and repetition. It localises to the Broca's area in the left posterior inferior frontal gyrus.

In transcortical motor aphasia, which localises to the anterior superior frontal lobe, the patient has good comprehension and repetition but has halting, effortful speech. Patients also have impaired writing skills.

Transcortical sensory aphasia is characterised by impaired auditory comprehension with intact repetition and fluent speech, and is caused by damage to the temporal lobes. It differs from Wernicke's aphasia in that patients still have intact repetition, and exhibit echolalia (the compulsive repetition of words). Improvement may be seen with speech therapy.

Anomic aphasia (also known as nominal aphasia) results in word finding difficulties. On closer examination there may also be repetition problems and comprehension problems but these are typically mild compared to other aphasia syndromes.

This scenario describes conduction aphasia. It is characterised by frequent speech errors, impaired repetition, reduced phonological short-term memory and naming difficulties.

In contrast to other forms of dysphasia, speech output is otherwise fluent and grammatically correct. Comprehension is intact. It is thought to be caused by left temporo-parietal region damage.

[Q: 4281] OnExamination 2012 - Neurology

A 72-year-old man with a history of type 2 diabetes mellitus and multiple transient ischaemic attacks (TIAs) comes to the hospital complaining of visual field loss. He says this happened suddenly and he woke up with problems with his vision the morning before coming to the Emergency department.

Medication includes clopidogrel, ramipril, atorvastatin, and metformin.

On examination his BP is 165/100 mmHg, his pulse is 76 and regular. Visual field examination reveals a right homonymous upper quadrantanopia.

Where is the most likely site for the underlying lesion?

- 1- Left occipital lobe
- 2- Left temporal lobe
- 3- Optic chiasm
- 4- Right optic nerve
- 5- Right temporal lobe

Answer & Comments

Answer: 2- Left temporal lobe

Temporal lobe lesions result in a bilateral homonymous hemianopia.

Occipital lobe lesions result in cortical blindness.

The most likely cause in this case is a thromboembolic event affecting the left temporal lobe. Given he has suffered multiple TIAs he should be considered for a work up including echocardiogram and carotid USS.

Anti-platelet management if tolerated should be with aspirin and dipyridamole as per the ESPS2 trial.

[Q: 4282] OnExamination 2012 - Neurology

A 50-year-old gentleman presents to the emergency department having had a fall.

Examination revealed ataxia and some mild extrapyramidal signs. He was receiving treatment for suspected Parkinson's disease following a fall he had had six months ago when he demonstrated extrapyramidal signs. His symptoms had been noted to have improved with the medication. Tilt table testing was performed and found to be positive.

What is the likely diagnosis?

- 1- Cerebellar degeneration
- 2- Multi-system atrophy
- 3- Parkinson's disease
- 4- Postural hypotension
- 5- Wilson's disease

Answer & Comments

Answer: 2- Multi-system atrophy

Multi-system atrophy includes three syndromes that usually overlap

Striatal degeneration leading to parkinsonism

Autonomic failure

Olivopontocerebellar degeneration.

The average age of onset is 50 years (earlier than in Parkinson's disease) and the median survival six to nine years. It runs a briefer course than Parkinson's disease.

The clinical presentation is highly varied and may begin with any of the above clinical signs. The unifying pathologic hallmark is the

presence of a-synuclein-positive inclusions located in various brain regions.

Early in the course of the illness parkinsonian features may respond to dopaminomimetic agents. These have to be used with caution due to their tendency to provoke orthostatic hypotension.

[Q: 4283] OnExamination 2012 - Neurology

A 23-year-old male is admitted following an altercation in which he is stabbed in the thigh by a bottle.

Which of the following features suggests injury to the femoral nerve?

- 1- Loss of knee reflex
- 2- Loss of sensation over lateral aspect of thigh
- 3- Weakness of abduction of the hip
- 4- Weakness of adduction at the hip
- 5- Weakness of knee flexion

Answer & Comments

Answer: 1- Loss of knee reflex

A lesion of the femoral nerve (L2/3/4) is characterised by weakness of the quadriceps femoris muscle and hence weakness of extension of the knee, loss of sensation over the front of the thigh and loss of the knee jerk.

The obturator nerve (L2-4) supplies adductors of hip and lateral cutaneous nerve to thigh supplies sensation to the outer part of the thigh.

[Q: 4284] OnExamination 2012 - Neurology

A 18-year-old man is referred with a six month history of daily headache which is mostly frontal in location and occasionally associated with nausea. He has been taking

paracetamol 3 g/day, aspirin 300 mg thrice daily and codeine 40 mg thrice daily, which has only a temporary effect.

He has a two year history of depression, treated with paroxetine. No abnormalities were found on examination.

What is the most likely diagnosis?

- 1- Analgesic misuse headache
- 2- Cerebral tumor
- 3- Cluster headache
- 4- Headache due to depression
- 5- Migraine

Answer & Comments

Answer: 1- Analgesic misuse headache

The two commonest causes of chronic daily headache are tension type headache and analgesic misuse headache.

The latter is the most likely diagnosis for this patient's symptoms.

It usually occurs as a result of chronic use of analgesics such as codeine phosphate and paracetamol.

Typically the headache is relieved with the analgesics just to return in the next hours.

The treatment of choice is the slow reduction and withdrawal of analgesics.

[Q: 4285] OnExamination 2012 - Neurology

A 60-year-old man presents with an episode of memory loss. Three days earlier he had become confused. His wife led him into the house - he apparently sat down at her request, and had a cup of tea. He then wandered around the house, confused, but remained conscious and able to have some conversation with his wife, though continuing to ask similar questions repeatedly.

After three hours, he abruptly returned to normal and had no recollection of the events.

What is the most likely diagnosis?

- 1- Alcohol related amnesia
- 2- Chronic subdural haematoma
- 3- Complex partial status epilepticus
- 4- Hysterical fugue state
- 5- Transient global amnesia

Answer & Comments

Answer: 5- Transient global amnesia

This is the typical clinical description of transient global amnesia which represents a transient vascular insufficiency of both hippocampi.

[Q: 4286] OnExamination 2012 - Neurology

A 70-year-old man presents with difficulty speaking.

He has a history of diabetes, hypertension, hypercholesterolaemia, chronic obstructive pulmonary disease. He is currently on aspirin, simvastatin, amlodipine and hydrochlorothiazide.

On examination the patient is awake, his blood pressure is 150/70 mmHg. His pulse is irregularly irregular. He has 4/5 strength on the right arm and leg and 5/5 strength on the left.

When asked to point to the window he appears unable to do so. When told to raise his arms and place his hands out he does not. When visually shown the same action he is able to perform it. When asked to repeat 'Today is a sunny day', he is able to do so.

With what is this type of dysphasia consistent?

- 1- Broca's aphasia
- 2- Global aphasia
- 3- Transcortical motor aphasia

- 4- Transcortical sensory aphasia
- 5- Wernicke's aphasia

Answer & Comments

Answer: 4- Transcortical sensory aphasia

In Broca's or non-fluent or expressive aphasia the patient is unable to name objects with poor comprehension and repetition. It localises to the Broca's area in the left posterior inferior frontal gyrus.

In Wernicke's or fluent or receptive aphasia the patient is able to form correct grammatical sentences but language content is incorrect. It localises to the dominant superior temporal gyrus. There is poor comprehension and repetition but verbal output is fluent.

In transcortical motor aphasia, which localises to the anterior superior frontal lobe, the patient has good comprehension and repetition but has halting, effortful speech. Patients also have impaired writing skills.

Global aphasia results in an almost mute patient: there is poor verbal output, comprehension, repetition and understanding.

Transcortical sensory aphasia is what is described in this case. It is characterised by impaired auditory comprehension with intact repetition and fluent speech, and is caused by damage to the temporal lobes. It differs from Wernicke's aphasia in that patients still have intact repetition, and exhibit echolalia (the compulsive repetition of words). Improvement may be seen with speech therapy.

[Q: 4287] OnExamination 2012 - Neurology

A 65-year-old woman has a one month history of malaise, weight loss, right sided pain around the eye and headaches. She has also noticed intermittent diplopia.

Five years previously she had a mastectomy for carcinoma of the breast.

On examination, temperature was 37.5°C, there was tenderness of the scalp on the right forehead and temple, and some minor weakness of abduction of the right eye. ESR 55 mm/hour.

What is the most likely diagnosis?

- 1- Frontal sinusitis
- 2- Giant cell arteritis
- 3- Meningeal metastatic disease
- 4- Posterior communicating artery aneurysm
- 5- Thyroid eye disease

Answer & Comments

Answer: 2- Giant cell arteritis

The clinical description is classic for giant cell arteritis.

It should always be considered in elderly patients with headaches, ocular symptoms, systemic symptoms and high erythrocyte sedimentation rate.

[Q: 4288] OnExamination 2012 - Neurology

A 79-year-old woman has had worsening shortness of breath for several years.

She now has to sleep sitting up on two pillows. She has difficulty swallowing. There is no history of chest pain. She is afebrile.

Recently, she suffered a stroke with left hemiparesis. A chest x ray reveals a near-normal left ventricular size with a prominent left atrial border.

Which of the following conditions is most likely to account for these findings?

- 1- Aortic coarctation
- 2- Cardiomyopathy
- 3- Essential hypertension
- 4- Left renal artery stenosis

- 5- Mitral valve stenosis

Answer & Comments

Answer: 5- Mitral valve stenosis

Mitral valve stenosis leads to left atrial enlargement, but the left ventricle is usually small.

An enlarged left atrium may lead to pressure posteriorly on the oesophagus.

Most mitral valvular disease in adults results from rheumatic heart disease.

[Q: 4289] OnExamination 2012 - Neurology

A 60-year-old man was brought to casualty after a fall in his bathroom.

Seen immediately by his family, he was already picking himself up from the floor and said he was not injured. His wife felt that he was transiently dazed.

On examination, he was alert, and no abnormalities were noted. His medical history included a history of hypertension for which he was taking bendroflumethiazide 2.5 mg daily. He was discharged without any further intervention.

Two weeks later his wife brings the patient to see you because the dazed state has returned. Examination reveals a temperature of 36.7°C, a pulse rate of 84 bpm regular, a blood pressure of 152/94 mm Hg. On questioning he is slightly slowed, being disoriented to time with some deficit in recent memory. The patient moves slowly, but power is normal. Neurologic examination shows slight hyperactivity of the tendon reflexes on the right with unclear plantar responses because of bilateral withdrawal.

Which of the following would you request?

- 1- 24-hour ambulatory electrocardiogram
- 2- CSF analysis
- 3- CT of the head

- 4- EEG
- 5- Electromyography and nerve conduction testing

Answer & Comments

Answer: 3- CT of the head

This patient probably has evidence of a right sided hemiparesis and together with the history of confusion and previous head injury a diagnosis of subdural haematoma should be suspected.

Consequently the most appropriate investigation would be CT headscan.

Particularly in the presence of focal neurology, a CT scan should be performed before embarking upon a lumbar puncture.

[Q: 4290] OnExamination 2012 - Neurology

Which of the following statements regarding hiccup is true?

- 1- Is caused by a tonic relaxation of the diaphragm.
- 2- Is commonly caused by local irritation to the vagus nerve.
- 3- Can reliably be treated with theophylline.
- 4- May be caused by a foreign body in the nose.
- 5- May be caused by a posterior fossa tumour.

Answer & Comments

Answer: 5- May be caused by a posterior fossa tumour.

Hiccup is caused by frequent or rhythmic clonic contraction of the diaphragm. When prolonged, other causes should be considered including:

CNS disease: Posterior fossa tumour, brain injury, encephalitis

Phrenic nerve or diaphragm irritation: Tumour, pleurisy, pneumonia, intrathoracic adenopathy, pericarditis, gastro-oesophageal reflux, oesophagitis

Systemic causes: Alcohol intoxication, uraemia

Other: Foreign body or insect in the ear.

In infants it may be associated with apnoea or hyperventilation.

Folk remedies include aerophagia, breath holding, pharyngeal stimulation, distraction.

Haloperidol, metaclopramide and several anaesthetic agents are also said to work.

[Q: 4291] OnExamination 2012 - Neurology

A 60-year-old woman presents with a 24 hours history of headache and vomiting. She has been on steroids for temporal arteritis for the last three years.

Examination demonstrates pyrexia, neck stiffness, photophobia, dysarthria, nystagmus and ataxia. CSF shows neutrophilic pleocytosis, low glucose, elevated protein.

What is the most likely diagnosis?

- 1- Carcinomatosis meningitis
- 2- Cryptococcal meningitis
- 3- Listeria meningitis
- 4- Meningococcal meningitis
- 5- Tuberculous meningitis

Answer & Comments

Answer: 3- Listeria meningitis

Risk factors for listeria meningitis include older age and immunosuppression.

It is typically associated with brain stem signs.

Cerebrospinal fluid shows

Neutrophilic pleocytosis

Low glucose and

High protein.

[Q: 4292] OnExamination 2012 -
Neurology

A 63-year-old male is admitted with acute onset unsteadiness of gait, dizziness and dysphagia.

Examination revealed a right-sided Horner's syndrome, nystagmus, loss of pain and temperature sensation on the left side of the trunk and in the left arm and leg, and gait ataxia.

What is the most likely diagnosis?

- 1- Leaking posterior communicating artery aneurysm
- 2- Left sided acoustic neuroma
- 3- Posterior inferior cerebellar artery occlusion
- 4- Right sided pontine infarct
- 5- Spontaneous left sided cerebellar haemorrhage

Answer & Comments

Answer: 3- Posterior inferior cerebellar artery occlusion

This is Wallenberg's syndrome/lateral medullary syndrome and is due to occlusion of the posterior inferior cerebellar artery.

[Q: 4293] OnExamination 2012 -
Neurology

A 52-year-old man has a slurring of his speech.

Examination reveals bilateral partial ptosis and frontal balding, and difficulty releasing his grip after shaking hands.

What is the most likely diagnosis?

- 1- Duchenne muscular dystrophy
- 2- Eaton-Lambert syndrome

3- Myasthenia gravis

4- Myotonia dystrophica

5- Myotonia congenita

Answer & Comments

Answer: 4- Myotonia dystrophica

Myotonia dystrophica is autosomal dominant.

Its features include:

Ptosis

Frontal balding

Cataracts

Cardiomyopathy

Impaired intellect

Testicular atrophy

Diabetes mellitus and

Slurred speech (from tongue and pharyngeal myotonia).

There is no treatment for weakness which is the main cause of disability, but phenytoin, quinine or procainamide may be useful for myotonia.

Myotonia congenital (Thomsen's disease) is not associated with features of myotonia dystrophica apart from difficulty relaxing after forceful contraction.

[Q: 4294] OnExamination 2012 -
Neurology

A 27-year-old man presents with a two year history of intermittent tingling sensation involving his left side.

It starts in his fingers and spreads in 10-20 seconds to affect the whole arm and leg on the same side. The attacks only last for one minute.

Which of the following is the most likely diagnosis?

- 1- Hyperventilation
- 2- Migraine with aura
- 3- Multiple sclerosis
- 4- Somatosensory seizures
- 5- Transient ischaemic attacks

Answer & Comments

Answer: 4- Somatosensory seizures

Positive symptoms (jerking, tingling) usually signify epilepsy.

Negative symptoms (weakness, numbness) are usually caused by transient focal ischaemia.

Spread of symptoms ('marching') indicates migraine (in 5-20 minutes) or seizures (in seconds).

The usual source of somatosensory seizures is the parietal lobe.

[Q: 4295] OnExamination 2012 - Neurology

A 19-year-old woman presents to the clinic having had five blackouts over the last year, all while she is standing up.

She gets warnings of blurred vision, nausea, and feeling hot. She has been witnessed twice to have jerking of all limbs while she is unconscious. The attacks last 30 to 60 seconds.

She recovers quickly after the attacks. She has never bitten her tongue or sustained any injuries.

Physical examination and an ECG are normal. Her grandmother and sister suffer from epilepsy.

Which of the following investigations is the most appropriate?

- 1- 24 hour ECG recording
- 2- CT brain
- 3- ECHO

- 4- EEG
- 5- Tilt table test

Answer & Comments

Answer: 5- Tilt table test

The most likely diagnosis is vasovagal syncope.

The gradual onset of the attack is typical. It is common for patients with syncope to have jerking of their limbs while they are unconscious.

Warning symptoms of darkening/blurring of vision, dizziness and feeling hot are characteristic in syncope. Patients usually recover very quickly after the event.

Tilt table test is a useful test to support the diagnosis of vasovagal syncope.

[Q: 4296] OnExamination 2012 - Neurology

Which of the following is caused by a lesion of the occipital lobe?

- 1- Acalculia
- 2- Astereognosis
- 3- Constructional apraxia
- 4- Cortical blindness
- 5- Visuospatial neglect

Answer & Comments

Answer: 4- Cortical blindness

Lesions of the frontal lobe include difficulties with task sequencing and executive skills:

Expressive aphasia (receptive aphasia a temporal lobe lesion)

Primitive reflexes

Perseveration (repeatedly asking the same question or performing the same task)

Anosmia

Changes in personality.

Lesions of the parietal lobe include:

Apraxias

Neglect

Astereognosis (unable to recognise an object by feeling it)

Visual field defects (typically homonymous inferior quadrantanopia).

They may also cause acalculia (inability to perform mental arithmetic).

Lesions of the temporal lobe cause:

Visual field defects (typically homonymous superior quadrantanopia)

Wernicke's (receptive) aphasia

Auditory agnosia

Memory impairment.

Occipital lobe lesions include:

Cortical blindness (blindness due to damage to the visual cortex and may present as Anton syndrome where there is blindness but the patient is unaware or denies blindness)

Homonymous hemianopia

Visual agnosia (seeing but not perceiving objects - it is different from neglect, since in agnosia the objects are seen and followed but cannot be named).

[Q: 4297] OnExamination 2012 - Neurology

A 75-year-old woman presents with a two month history of episodic loss of vision in her right eye. Her electrocardiogram was normal and carotid ultrasound reveal a 49% stenosis of the right internal carotid artery, as assessed by the NASCAT criteria.

What is the most appropriate treatment for this patient?

1- Aspirin

2- Carotid endarterectomy

3- Dipyridamole

4- Clopidogrel

5- Warfarin

Answer & Comments

Answer: 1- Aspirin

Current NICE guidelines recommend that patients who have had a suspected TIA who are at high risk of a stroke (ABCD score of 4 or above) should have aspirin (300mg OD) started immediately. They also need specialist assessment and investigation within 24 hours of onset of symptoms. Secondary prevention measures should be introduced as soon as the diagnosis is confirmed, with consideration of individual risk factors.

The ABCD scoring system uses:

Age ≥ 60 ? (1)

BP $\geq 140/90$ mmHg at initial evaluation (1)

Clinical features (unilateral weakness 2, isolated speech disturbance 1, other 0)

Duration of symptoms (≥ 60 minutes, 10-59 minutes, <10 minutes)

Diabetes mellitus (1)

Although you cannot calculate the ABCD score with the information given in this question, aspirin remains the most appropriate answer.

Carotid endarterectomy has been established as an effective treatment for both symptomatic patients and asymptomatic patients who are shown to have carotid artery stenosis. It reduces the risk of disabling stroke or death by 48% in a person with severe symptomatic carotid stenosis ($>70\%$) who has had a TIA. The peri-operative risk of disabling stroke or death is approximately 3%. Current UK guidelines recommend endarterectomy for symptomatic patients

with greater than 70% stenosis, based on the North American Symptomatic Carotid Endarterectomy Trial which showed clear benefit. The endarterectomy should be performed as soon as the patient is fit for surgery, preferably within two weeks of a TIA.

The benefit is marginal for symptomatic patients with 50-69% stenosis, but may be greater in male patients. NICE recommends these patients are also considered for endarterectomy. There is significantly less benefit for asymptomatic patients, even those with greater than 60% stenosis. Patients with less than 50% stenosis should not be considered for carotid surgery

Recurrent stenosis can occur in 1-20% of patients following endarterectomy, and re-operation is needed in 1-3% of cases. Ipsilateral strokes occur in 9% of patients following endarterectomy, and 26% of those treated with medical management alone (within 2 years).

All patients with suspected non-disabling stroke or TIA who are considered as candidates for carotid endarterectomy should have carotid imaging within 1 week. If the patient has had a disabling stroke there is no real benefit in them undergoing the procedure.

Modified-release dipyridamole is indicated in combination with aspirin only once a TIA has been confirmed by a specialist. Alone, it is recommended only if aspirin is contraindicated or not tolerated.

Clopidogrel is recommended in patients who have had an ischaemic stroke, rather than a TIA.

Warfarin is only indicated with cerebral venous sinus thrombosis, or if the patient has atrial fibrillation.

* please note for this explanation we have used the North American Symptomatic Carotid Endarterectomy Trial (NASCET)

criteria, as opposed to the European Carotid Surgery Trialists' Collaborative Group (ECST) criteria when discussing carotid endarterectomy. Patients should be considered for endarterectomy if they have symptomatic carotid stenosis of 70-99% as assessed according to the ECST criteria. Carotid imaging reports will state which criteria are being used.

[Q: 4298] OnExamination 2012 - Neurology

A 72-year-old lady has four months of memory loss, urinary incontinence and falls.

On examination she has mild memory loss and a broad-based, slow gait. Muscle tone is normal and both plantar reflexes are downgoing.

What is the likely diagnosis?

- 1- Alzheimer's disease
- 2- Frontal lobe dementia
- 3- Multi-infarct dementia
- 4- Normal-pressure hydrocephalus
- 5- Parkinson's disease

Answer & Comments

Answer: 4- Normal-pressure hydrocephalus

Normal-pressure hydrocephalus is characterised by abnormal gait, urinary incontinence, and dementia.

It is an important clinical diagnosis, because it is a potentially reversible cause of dementia.

It is important to distinguish it from Parkinson's disease.

The onset of gait disturbance and urinary symptoms is unusual so early in dementia.

Frontal lobe dementia is characterised by loss of 'executive' functions and multi-infarct state usually has a step-wise history.

[Q: 4299] OnExamination 2012 -
Neurology

A 35-year-old woman has noticed increased clumsiness and tremor.

She has recently broken up with her partner because he found her increasingly argumentative. She has no past medical history and takes no prescribed or recreational drugs.

There is a family history of liver cirrhosis in her grandfather, who drank four bottles of whisky per week. She reports drinking less than four units per week.

What is the likely cause for her tremor?

- 1- Alcohol abuse
- 2- Huntington's disease
- 3- Lewy body dementia
- 4- Multiple sclerosis
- 5- Wilson's disease

Answer & Comments

Answer: 5- Wilson's disease

Wilson's disease is an autosomal recessive condition which causes build up of copper in the body. Copper accumulates in the liver and brain. This results in hepatitis, liver failure or cirrhosis. Accumulation in the brain can result in behavioural changes, depression, seizures, parkinsonism, however the initial sign is usually increased clumsiness.

This woman's tremor, clumsiness and behavioural change could be put down to alcohol abuse. Given the family history of cirrhosis it would be important to rule out Wilson's disease before accusing her of alcohol problems.

Huntington's disease is a neurodegenerative genetic disorder that is autosomal dominant. The features are of choreiform movements, problems with coordination and walking, behavioural and psychiatric problems. The

disease leads eventually to dementia and premature death.

Lewy body dementia is a mixture of Alzheimer's disease with Parkinson's disease. The main features are fluctuating cognition and alertness from hour to hour, visual hallucinations (usually of animal or human, and the patient may have insight into these hallucinations) and motor features of Parkinson's disease.

Multiple sclerosis would present in this age group and sex. It is due to autoimmune mediated demyelination. To make the diagnosis there must be two separate attacks separated in time and space (that is, affecting two different nerves and on two separate occasions).

The commonest signs and symptoms are

Optic neuritis

Sensory loss

Spinal cord symptoms with spasticity

Autonomic dysfunction of bladder and bowel

Constitutional symptoms such as fatigue and depression.

[Q: 4300] OnExamination 2012 -
Neurology

A 48-year old alcoholic man presents with gradually increasing confusion and drowsiness over the past two weeks.

He had previously attended the Emergency department having fallen over drunk, but had discharged himself before being reviewed by a doctor.

On examination he has multiple old bruises including one to his right arm and to the right side of his face above his eye. His BP is 150/82 mmHg, his pulse is 67 and irregular. There is 3/5 power weakness of his left arm, he is drowsy and confused.

Investigations show:

Haemoglobin 10.2 g/dl(13.5-17.7)
 White cell count $12.3 \times 10^9/L$ (4-11)
 Platelets $121 \times 10^9/L$ (150-400)
 Sodium 133 mmol/l (135-146)
 Potassium 3.9 mmol/l (3.5-5)
 Creatinine 90 $\mu\text{mol/l}$ (79-118)
 ALT 190 U/l (5-40)

Which of the following is the most appropriate intervention?

- 1- CT head
- 2- IV broad spectrum antibiotics
- 3- Lumbar puncture
- 4- Ultrasound abdomen
- 5- Upper GI endoscopy

Answer & Comments

Answer: 1- CT head

The suspicion is that this patient has a subdural haematoma. In patients with alcoholism who are more likely to have abnormal clotting, what seems like a very minor, innocuous injury may lead to a potentially serious bleed. CT head is the initial investigation of choice.

Whilst sepsis is possible, we have no indication on initial findings of a source of infection, therefore antibiotics are not appropriate.

A lumbar puncture should also be avoided until after CT head.

An ultrasound, whilst it would confirm liver changes, is unlikely to be helpful in the acute stage, and the anaemia is likely to be chronic, rather than due to an acute bleed.

[Q: 4301] OnExamination 2012 - Neurology

An 80-year-old man comes to the office to be evaluated for difficulty moving and memory

problems.

On examination he has mask-like facies and a pill-rolling tremor. His gait is bradykinetic. He is unable to look down and has been falling frequently only in the last few months. He is not orthostatic on examination

Which of the histopathological changes in this disease are similar to those found in the listed conditions?

- 1- Alzheimer's disease
- 2- Chronic progressive external ophthalmoplegia (CPEO)
- 3- Multiple system atrophy (MSA)
- 4- Prion disease
- 5- Tabes dorsalis

Answer & Comments

Answer: 1- Alzheimer's disease

Multiple system atrophy is an alpha-synucleinopathy.

Prion disease has spongiform changes.

CPEO is a mitochondrial disorder.

Tabes dorsalis is a result of inflammation from a syphilis infection.

[Q: 4302] OnExamination 2012 - Neurology

A 16-year-old girl presented with fever, headache and photophobia.

Investigations revealed:

Cerebrospinal fluid examination

Opening pressure 260 mm H₂O (50-180)

Total protein 0.8 g/l (0.15-0.45)

Glucose 4.2 mmol/l (3.3-4.4)

White cell count 60 per ml (<5)

Lymphocytes 90% (60-70)

Plasma glucose 6.4 mmol/l (3.0-6.0)

What is the most likely diagnosis?

- 1- Bacterial meningitis
- 2- Cryptococcal meningitis
- 3- Tuberculosis meningitis
- 4- Viral encephalitis
- 5- Viral meningitis

Answer & Comments

Answer: 5- Viral meningitis

Normal cerebrospinal fluid (CSF) glucose together with

A CSF lymphocytosis

An increased opening pressure, and

A raised CSF protein

are typical of a viral meningitis, which would be high on the list of differentials in patients of this age group (together with bacterial meningitis).

A handy guide to CSF findings

Read more about differential diagnoses from abnormal CSF values...

[Q: 4303] OnExamination 2012 - Neurology

A 70-year-old man has Parkinson's disease. He is started on treatment with L-dopa and dopa decarboxylase inhibitor therapy. However he continues to have troublesome tremor.

Which of the following drugs would be most likely to help?

- 1- Amantadine
- 2- Benzhexol
- 3- Propranolol
- 4- Ropinirole
- 5- Selegiline

Answer & Comments

Answer: 2- Benzhexol

Anticholinergic drugs such as benzhexol remain the treatment of choice in parkinsonian tremor.

L-dopa, selegiline and dopamine agonists are less effective in tremor.

Propranolol is the treatment of choice in essential tremor.

[Q: 4304] OnExamination 2012 - Neurology

A 77-year-old male presents with sudden loss of vision in his right eye, associated with a relative afferent pupillary defect. He has poorly controlled systemic hypertension and raised cholesterol.

What is the most likely aetiology of his presentation?

- 1- Cataract
- 2- Chronic open angle glaucoma
- 3- Macular degeneration
- 4- Retinal vascular occlusion
- 5- Retinitis pigmentosa

Answer & Comments

Answer: 4- Retinal vascular occlusion

The history of acute loss of vision affecting one eye suggests an acute vascular occlusion, especially given the associated vascular risks.

The others cause a more chronic visual loss.

[Q: 4305] OnExamination 2012 - Neurology

A 78-year-old woman presents with a six month history of episodes of giddiness and impaired consciousness.

Neurological examination is normal.

What is the most likely cause?

- 1- Alzheimer-type dementia
- 2- Chronic subdural haematoma

- 3- Creutzfeldt-Jakob disease
- 4- Depressive stupor
- 5- Normal pressure hydrocephalus

Answer & Comments

Answer: 2- Chronic subdural haematoma

Chronic subdural haematoma is a common manifestation of intermittent confusion or focal neurological deficit in the elderly population. It may mimic a stroke.

Alzheimer's dementia is usually associated with a slowly progressive cognitive impairment.

Normal pressure hydrocephalus presents with a triad of dementia, ataxia and urinary incontinence.

CJD usually presents with a rapidly progressive dementia associated with ataxia and myoclonus.

[Q: 4306] OnExamination 2012 - Neurology

A 35-year-old woman is referred with right eye pain that has deteriorated over the last week.

On examination she had a mild ptosis of the right eye and was aware of diplopia with vertical image separation on looking upwards. She also had weakness of elevation of the right eye.

What is the most likely diagnosis?

- 1- Cavernous sinus thrombosis
- 2- Graves' ophthalmopathy
- 3- Myasthenia gravis
- 4- Posterior communicating artery aneurysm
- 5- Sphenoid sinusitis

Answer & Comments

Answer: 4- Posterior communicating artery aneurysm

The signs are consistent with a partial third nerve palsy associated with periorbital pain.

In a young person a posterior communicating artery aneurysm needs to be excluded.

With cavernous sinus thrombosis one should expect some other signs such as periorbital swelling, proptosis, and conjunctival injection.

With Graves' eye disease one should expect proptosis and lid retraction.

Myasthenia gravis does not present with pain.

[Q: 4307] OnExamination 2012 - Neurology

A 42-year-old HIV-seropositive man presents to the emergency department with a two week history of global headache. His partner says that he has become increasingly confused and disorientated.

The patient's latest CD4 count, taken three weeks ago, was 50 cells/mm³. He had chosen not to take antiretroviral therapy, but was taking co-trimoxazole as prophylaxis against *Pneumocystis carinii* pneumonia.

On examination, he had mild weakness of his left arm and leg in all muscle groups and a right homonymous hemianopia. Fundoscopy was normal with no evidence of papilloedema. A CT scan of his brain showed several areas of low attenuation in both cerebral hemispheres, but there was no enhancement with contrast and no mass effect.

What is the most likely diagnosis?

- 1- Cerebral lymphoma
- 2- Cerebral toxoplasmosis
- 3- HIV encephalopathy
- 4- Neurosyphilis
- 5- Progressive multifocal leukoencephalopathy

Answer & Comments

Answer: 5- Progressive multifocal leukoencephalopathy

The most likely diagnosis is progressive multifocal leukoencephalopathy (PML), a demyelinating disease seen in advanced HIV/AIDS and caused by the JC virus.

Cerebral lymphoma and cerebral toxoplasmosis are often associated with mass effect on CT brain scanning. In CNS lymphoma there is usually a solitary lesion. Cerebral toxoplasmosis is frequently associated with multiple lesions that show ring enhancement with IV contrast.

HIV encephalopathy may be associated with confusion, but is not associated with this CT appearance. This is not a typical presentation of neurosyphilis in any of its forms.

[Q: 4308] OnExamination 2012 - Neurology

A 29-year-old lady presented to the Emergency department with a diagnosis of DVT.

She is in the third trimester of her first pregnancy and she has been 'taking it easy' by resting a lot at home.

In the department she develops a right hemiparesis.

Which of the following is the most likely underlying cardiac abnormality?

- 1- Patent ductus arteriosus
- 2- Patent foramen ovale
- 3- Primum atrial septal defect
- 4- Secundum atrial septal defect
- 5- Ventricular septal defect

Answer & Comments

Answer: 2- Patent foramen ovale

This is a 'paradoxical embolus' where a right sided thrombus has crossed into the arterial circulation.

The commonest cause is a patent foramen ovale. Although atrial septal defects are also a cause, they are more rare.

[Q: 4309] OnExamination 2012 - Neurology

Which of the following is not a recognised association of acromegaly?

- 1- Elevated serum phosphate levels
- 2- Goitre
- 3- Hypertension
- 4- Pseudogout
- 5- Reduced serum prolactin levels

Answer & Comments

Answer: 5- Reduced serum prolactin levels

Pseudogout is seen in acromegaly but not gout. Hypertension, heart failure and cardiomyopathy may occur.

Goitre is seen in 20%, along with other soft tissue swelling.

Phosphate levels are elevated but calcium levels are not significantly increased.

Thirty percent have

Elevated prolactin levels

A combination of a damaged pituitary stalk reducing the dopamine suppression signal, and

Reduced thyroid-stimulating hormone levels leading to increased thyrotropin-releasing hormone which stimulates prolactin secretion.

[Q: 4310] OnExamination 2012 - Neurology

A 25-year-old male presents with an eight

week history of difficulty walking.

On examination he had increased tone and pyramidal weakness of the right leg. There was impairment of pinprick sensation in the left leg up to the groin.

Which one of the following is the cause of these signs?

- 1- A central cauda equina lesion
- 2- A cervical spinal cord lesion
- 3- A lesion at the foramen magnum
- 4- A right sided thoracic spinal cord lesion
- 5- Bilateral cerebral hemisphere lesions

Answer & Comments

Answer: 4- A right sided thoracic spinal cord lesion

The clinical features suggest Brown-Sequard syndrome. A hemicord lesion causes it.

Ipsilateral signs include pyramidal weakness and dorsal column dysfunction (joint position and light touch) and contralateral signs include spinothalamic dysfunction (pinprick and temperature).

Causes include trauma, tumours, and multiple sclerosis.

[Q: 4311] OnExamination 2012 - Neurology

A 75-year-old female presents with an acute stroke and is noted to have a partial left homonymous hemianopia, a mild left hemiparesis and left hemisensory inattention.

Where on the right is the most likely area of infarction?

- 1- Frontal lobe
- 2- Medial temporal lobe
- 3- Occipital lobe
- 4- Parietal lobe
- 5- Thalamus

Answer & Comments

Answer: 4- Parietal lobe

A unilateral parietal lobe lesion, left or right, causes a contralateral hemihypesthesia, mild hemiparesis, parietal ataxia, homonymous hemianopia or inferior quadrantanopia and unilateral impairment of optokinetic nystagmus.

A left (usually dominant) parietal lesion causes the above signs in addition to sensory aphasia, Gerstmann syndrome (dysgraphia, dyscalculia, finger agnosia, left-right disorientation), bilateral apraxia and tactile agnosia.

A right (usually non-dominant) parietal lesion also causes left extinction phenomenon, left visual neglect, neglect of the left side of the body, anosognosia, impaired spatial processing and dressing apraxia.

Biparietal lesions result in markedly impaired orientation and spatial processing and ataxia.

An occipital lobe lesion usually causes contralateral homonymous hemianopia or quadrantanopsia. It does not typically cause hemiparesis or inattention.

Frontal lesions do not usually cause visual defects.

Temporal lobe lesions classically cause an homonymous superior quadrantanopsia. Again, there is not usually hemiparesis or inattention.

[Q: 4312] OnExamination 2012 - Neurology

A 40-year-old male presents to his GP with a two week history of numbness and a burning sensation on the lateral aspect of the left upper thigh.

Examination reveals sensory loss over the anterolateral thigh.

Which one of the following nerves is most likely to be involved in this patient?

- 1- Femoral nerve
- 2- L2 nerve root
- 3- L3 nerve root
- 4- Lateral cutaneous nerve of the thigh
- 5- Obturator nerve

Answer & Comments

Answer: 4- Lateral cutaneous nerve of the thigh

The pure sensory loss makes the diagnosis of meralgia paraesthetica and is a consequence of damage to the lateral cutaneous nerve of the thigh.

It is usually a consequence of entrapment at the lateral inguinal ligament or less likely, trauma, ischaemia or a retroperitoneal lesion.

[Q: 4313] OnExamination 2012 - Neurology

A teenage girl presents with Guillain-Barre syndrome (GBS).

Her weakness continues to worsen after admission to hospital.

Which of the following should be used to monitor her?

- 1- Arterial blood gases
- 2- Chest expansion size
- 3- FEV₁/FVC ratio
- 4- PEF
- 5- Vital capacity

Answer & Comments

Answer: 5- Vital capacity

This is the best way to monitor respiratory function in any neurological disorders that can affect the respiratory muscles (for example, GBS, myasthenia gravis).

[Q: 4314] OnExamination 2012 - Neurology

A 26-year-old previously healthy woman has a sudden onset of mental confusion.

She has a seizure and is brought to the hospital.

Her vital signs show blood pressure 100/60 mmHg, temperature 37°C, pulse 89, and respirations 22.

A lumbar puncture reveals a normal opening pressure, and clear, colourless cerebrospinal fluid (CSF) is obtained with 1 RBC and 20 WBCs (all lymphocytes), with normal glucose and protein.

An MRI scan reveals swelling of the right temporal lobe with haemorrhagic areas.

Which of the following infectious agents is the most likely cause for these findings?

- 1- Haemophilus influenzae
- 2- Herpes simplex virus
- 3- Influenza virus
- 4- Mycobacterium tuberculosis
- 5- Neisseria meningitidis

Answer & Comments

Answer: 2- Herpes simplex virus

Haemorrhagic lesions of the temporal lobe are typical for Herpes simplex virus infection.

Haemophilus influenzae is the organism most associated with meningitis in children.

Neisseria meningitidis would cause meningitis - however, in this case there are lymphocytes not neutrophils in the CSF and a normal, not low, glucose.

[Q: 4315] OnExamination 2012 - Neurology

Which statement is true regarding gabapentin?

- 1- Is a potent hepatic enzyme inducer

- 2- Is of particular value as monotherapy in absence attacks (petit mal)
- 3- Requires dose adjustment in renal disease
- 4- Side effects typically include visual field defects with long term use
- 5- Therapy is best monitored through measuring plasma concentrations

Answer & Comments

Answer: 3- Requires dose adjustment in renal disease

Gabapentin does not induce cytochrome P450 unlike other anticonvulsants such as phenytoin and phenobarbitone.

Vigabatrin may cause visual field defects, which may be irreversible. Rarely have visual disturbances been associated with gabapentin.

Gabapentin is no use in petit mal and is used for add-on therapy in partial or generalised seizures.

[Q: 4316] OnExamination 2012 - Neurology

Which of the following is true of tetanus?

- 1- Failure to culture Clostridium tetani from the wound would make the diagnosis doubtful
- 2- Infection confers lifelong immunity
- 3- There is a characteristic EEG
- 4- Clostridium-specific intravenous immunoglobulin is of no benefit once spasm has started
- 5- Cephalic tetanus causes severe dysphagia

Answer & Comments

Answer: 5- Cephalic tetanus causes severe dysphagia

A. Absence of a wound does not exclude tetanus.

B. Patients need to be actively immunised after recovery.

C. The toxin tetanospasmin does not cross the blood brain barrier, it diffuses through the blood to bind to receptors containing gangliosides on the neuronal membranes of presynaptic nerve terminals in muscles. The toxin does reach the brain by axonal transport.

D. It is ineffective once the toxin is attached to nervous tissue but may prevent progression.

E. Cephalic means involving the cranial nerves usually from a wound on the head and neck. It may be confused with rabies but hydrophobia never occurs. (OTM, 3e, 7.11.20)

[Q: 4317] OnExamination 2012 - Neurology

A 60-year-old male presents with a six month history of a gradually increasing burning sensation in his feet.

Examination revealed normal cranial nerves and higher mental function. He has normal bulk, tone, power, light touch and pinprick sensation, co-ordination and reflexes in upper and lower limbs.

With which of the following are these clinical findings consistent?

- 1- Diabetic amyotrophy
- 2- Large fibre sensory neuropathy
- 3- Motor neurone disease
- 4- Sjogren's syndrome
- 5- Small fibre sensory neuropathy

Answer & Comments

Answer: 5- Small fibre sensory neuropathy

The burning sensation described is typical of a neuropathy affecting the small unmyelinated and thinly myelinated nerve fibres.

General neurological examination and reflexes are usually normal in this type of neuropathy unless there is coexisting large (myelinated) fibre involvement.

Neuropathy affecting the large myelinated sensory fibres generally causes glove and socking sensory loss and loss of reflexes.

Conditions in which the small fibres are preferentially affected in the early stages include diabetes and amyloidosis. In the later stages however the neuropathy in these conditions also affects large fibres.

The neuropathy associated with Sjogren's syndrome is a pure sensory neuropathy (ganglionopathy).

[Q: 4318] OnExamination 2012 - Neurology

A 65-year-old man has a monotonous, slurred speech. He has an expressionless face and a festinant gait.

There is also impairment of vertical gaze.

What is the most likely underlying aetiology?

- 1- Cerebrovascular disease
- 2- Idiopathic
- 3- Shy-Drager syndrome
- 4- Steele-Richardson-Olszewski syndrome
- 5- Wilson's disease

Answer & Comments

Answer: 4- Steele-Richardson-Olszewski syndrome

Parkinson's disease is a triad of

Bradykinesia

Tremor and

Rigidity.

Speech may be slurred and without accents or emphasis. Impairment of vertical gaze suggests the diagnosis of Steele-Richardson-

Olszewski syndrome or supranuclear gaze palsy, which also cause pyramidal signs, dementia or frontal lobe syndrome.

Response to L-dopa is poor and median survival is about seven years.

Shy-Drager syndrome is associated with autonomic dysfunction and postural hypotension.

Wilson's disease presents in children and young adults with cirrhosis and parkinsonism, which later leads to dementia, dysphagia and immobility.

[Q: 4319] OnExamination 2012 - Neurology

A 36-year-old police officer presents with a three day history of slurred speech. She also complains of double vision and a sensation of breathlessness.

The oxygen saturations are 99% on air. Neurological examination reveals normal power, reflexes and plantar responses.

Which of the following would improve symptoms in this presentation?

- 1- G-CSF
- 2- Edrophonium
- 3- Non-steroidal anti-inflammatory drugs
- 4- Physiotherapy
- 5- Plasmapheresis

Answer & Comments

Answer: 2- Edrophonium

This lady has symptoms suggesting myasthenia gravis.

Her breathlessness is probably secondary to anxiety about the symptoms and associated hyperventilation.

Edrophonium (Tensilon) is sometimes used in the diagnosis of myasthenia gravis and would

be expected temporarily to improve symptoms.

[Q: 4320] OnExamination 2012 - Neurology

A 45-year-old man presents with an insidious onset of binocular horizontal diplopia and left sided facial pain.

On examination he has a left abducens nerve palsy and numbness over the maxillary division of the left trigeminal nerve.

Of the following which is the most likely anatomical site of his neurological lesion?

- 1- Cavernous sinus
- 2- Cerebellopontine angle
- 3- Midbrain
- 4- Petrous apex
- 5- Superior orbital fissure

Answer & Comments

Answer: 4- Petrous apex

In the pre-antibiotic era an abducens nerve palsy with ipsilateral pain and numbness was due to petrous osteitis (Gradenigo syndrome) but is now more likely the result of a meningioma or nasopharyngeal carcinoma of the petrous apex.

The cavernous sinus syndrome consists of variable involvement of

Oculomotor (III)

Trochlear (IV)

Abducens (VI)

Trigeminal (ophthalmic and maxillary division) (V) and

Oculo-sympathetic nerves.

The superior orbital fissure syndrome is similar to the cavernous sinus syndrome except for the presence of proptosis.

Lesions of the cerebellopontine angle causes compression of cranial nerves V (trigeminal), VII (facial) and VIII (vestibulocochlear).

Lesions of the midbrain cause a variety of symptoms, depending on the exact area affected.

[Q: 4321] OnExamination 2012 - Neurology

A 67-year-old man is admitted to the Emergency department with drooling, tongue and lip swelling and tachypnoea. He has COPD, angina, diabetes and hypertension.

He was at home when the incident occurred, and had not recently been in contact with anything new. He has no known allergies and his medication has not changed in the past year.

What is the likely cause of his symptoms?

- 1- Aspirin
- 2- Diltiazem
- 3- Enalapril
- 4- Food allergy
- 5- Tetanus

Answer & Comments

Answer: 3- Enalapril

This gentleman has angioedema.

This is a side effect of angiotensin-converting enzyme inhibitor (ACEi) and to a lesser extent angiotensin receptor blocker (ARB). It does not necessarily occur as soon as the medication is started.

There is nothing pointing towards it being a food or drug allergy as he has not done anything different from normal.

Tetanus results in lock jaw and there is usually a history of injury.

The commoner side effects of diltiazem are leg swelling, bradycardia, AV node block and gastrointestinal (GI) disturbance.

The commoner side effects of aspirin are reflux or acid symptoms, with the possibility of GI bleed.

[Q: 4322] OnExamination 2012 -
Neurology

A 40-year-old man has been in a road traffic accident. His GCS is 8.

Which of the following could describe his condition?

- 1- A man lying still, eyes open and quiet. On questioning he appears confused. He is able to raise his eyebrows on command but cannot move his arms or legs at all. An MRI has shown damage to his spinal cord at C3.
- 2- A man lying still, eyes shut and groaning. Not responding to voice. On firm nail bed pressure he opens his eyes and withdraws his hand.
- 3- A man lying still, eyes shut, not making any noise. On command he opens his eyes and raises his hands but still makes no sound.
- 4- A man writhing around, eyes open and calling out obscenities. He smells strongly of alcohol. He variably obeys verbal commands.
- 5- A man writhing around, eyes open and screaming. Not responding to voice or following commands. On firm nail bed pressure he pushes your hand away.

Answer & Comments

Answer: 2- A man lying still, eyes shut and groaning. Not responding to voice. On firm nail bed pressure he opens his eyes and withdraws his hand.

The Glasgow coma scale (GCS) can be useful as a predictor of outcome and a way to

measure and monitor patients with reduced consciousness.

It is made up of three components: Eye opening, best verbal response and best motor response. Each of these is scored.

Eye opening:

Spontaneously = 4

To speech = 3

To painful stimulus = 2

No response = 1

Best verbal response:

Orientated = 5

Disorientated = 4

Inappropriate words = 3

Incomprehensible sounds = 2

No response = 1

Best motor response:

Obeys verbal commands = 6

Localises painful stimuli = 5

Withdrawal to pain = 4

Flexion to pain = 3

Extension to pain = 2

No response = 1

The Glasgow coma scale defines coma as E = 2, M = 4, V = 2 or less.

The GCS is meaningless unless it is broken down into its components.

The GCS is unreliable and should not be applied to patients who are inebriated, intubated or who have a therapeutic or traumatic paralysis.

A. This is not the correct answer. This man may well have a high C-spine lesion so the GCS score is unreliable. He would score 4 for eyes and 4 for verbalisation. You could argue

that raising his eyebrows on command is a best motor response of 5, or give him a score of 1 for not being able to move his limbs on command.

B. . E = 2, V = 2, M = 4.

C. This is not the correct answer. E = 3, V = 1, M = 5.

D. This is not the correct answer. This man sounds as though he may be drunk making the GCS unreliable. From the description, taking his best verbal and motor skills his GCS is E = 4, V = 4-5 (depending on the context and content of the obscenities), M = 6.

E. This is not the correct answer. E = 4, V = 2, M = 5.

[Q: 4323] OnExamination 2012 - Neurology

A 60-year-old male is accompanied to the office by his wife who has noticed that his memory is deteriorating. She also reports that at dinner parties he is inappropriate in his behavior and she thinks that his personality has changed.

On examination the patient has frontal lobe release signs. He is hypotonic in the arms but his reflexes are brisk. He has fasciculations in the tongue and in all four limbs.

You suspect frontotemporal dementia (FTD) with amyotrophic lateral sclerosis (ALS).

On which chromosome is the responsible gene located?

- 1- Chromosome 3
- 2- Chromosome 9
- 3- Chromosome 17
- 4- Chromosome 19
- 5- Chromosome 22

Answer & Comments

Answer: 2- Chromosome 9

Although frontotemporal dementia is associated with chromosome 17, when there is motor neuron disease (MND) associated the chromosome linked to the disorder is 9.

[Q: 4324] OnExamination 2012 - Neurology

A 74-year-old man comes to the clinic with his wife. He has been suffering from increasingly frequent falls and now has marked problems with his mobility.

Past history of note includes an inferior MI and TIA a few years earlier. He has also suffered from two episodes of urinary retention and now has an indwelling catheter.

On examination his BP is 142/72 mmHg, with a postural drop of 30 mmHg on standing. He has a quiet ejection systolic murmur, his chest is clear, and abdominal examination is unremarkable.

Neurological examination reveals loss of upward gaze, cogwheel rigidity and bradykinesia. He has a mild tremor only.

Investigations show

Haemoglobin 12.8 g/dl(13.5-17.7)

White cells $5.3 \times 10^9/L$ (4-11)

Platelets $221 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.7 mmol/l (3.5-5)

Creatinine 138 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely diagnosis?

- 1- Idiopathic parkinsonism
- 2- Lewy body disease
- 3- Multi-infarct disease
- 4- Multi-system atrophy
- 5- Pick's disease

Answer & Comments

Answer: 4- Multi-system atrophy

The particular features of autonomic dysfunction seen here, with postural hypotension and urinary retention, coupled with the loss of upward gaze and parkinsonism point towards a diagnosis of multi-system atrophy.

As here, whilst the motor symptoms are parkinsonian in nature, the tremor is often less pronounced than in a patient with idiopathic Parkinson's.

The Parkinson's symptoms associated with multi-system atrophy usually respond poorly to dopamine agonists or L-dopa, in contrast to idiopathic Parkinson's.

Urinary retention can be managed with an indwelling catheter if required, and postural hypotension managed with support stockings plus mineralocorticoids if required.

[Q: 4325] OnExamination 2012 - Neurology

A 35-year-old man presents to the Emergency department complaining of severe pain in his lower back after lifting a heavy box at work. The pain radiates to his right buttock and thigh. He has had no urinary symptoms.

On examination he can straight leg raise to 90 degrees on the left side but only to 30 degrees on the right. Sciatic stretch test is positive.

He has difficulty plantarflexing his right ankle and has abnormal sensation on the plantar aspect of the foot. His right ankle reflex is absent but all other reflexes are normal. There is no other sensory disturbance.

What is the likely diagnosis?

- 1- Cauda equina syndrome
- 2- L3/L4 disc prolapse
- 3- L4/L5 disc prolapse
- 4- L5/S1 disc prolapse
- 5- Old Shuerman's disease

Answer & Comments

Answer: 4- L5/S1 disc prolapse

An L5/S1 disc prolapse affects the S1 nerve root causing

Sensory loss to the posterior calf and the plantar surface of the foot

Motor loss to gastrocnemius and soleus and

Loss of ankle jerk.

[Q: 4326] OnExamination 2012 - Neurology

A 34-year-old male presents with weakness of the right hand. You note global wasting of the small hand muscles, there is also sensory loss over the medial border of the forearm and hand.

He says he was climbing a tree to rescue a kite and fell. Whilst falling he grabbed a branch and this pulled on his arm.

Injury to which of the following structures is the most likely explanation of this clinical presentation?

- 1- Cervical spine
- 2- Lower brachial plexus
- 3- Median nerve in the forearm
- 4- Radial nerve in the upper arm
- 5- Ulnar nerve at the elbow

Answer & Comments

Answer: 2- Lower brachial plexus

This is a classic story of a lower brachial plexus injury; sudden upward movement of the abducted arm. This causes features of an ulnar nerve palsy which is supplied by the lower brachial plexus roots C8 and T1.

The median and radial nerves can be excluded because of the typical ulnar nerve findings.

The ulnar nerve can be damaged at the elbow from chronic pressure, leaning on the elbows, and direct trauma.

However, this injury is a stretching injury of the arm.

A cervical spine injury would be expected to have other associated neurological signs.

[Q: 4327] OnExamination 2012 - Neurology

A 45-year-old woman presents to the Emergency department complaining of a severe headache and vomiting for 12 hours.

She was previously well and takes no medication.

On examination, her temperature was 37.5°C, her pulse rate was 110 beats per minute and her blood pressure was 95/60 mmHg. There was some neck stiffness and there was a right third nerve palsy with pupillary involvement.

Her initial investigations show:

Haemoglobin 13.6 g/dL (11.5-16.5)

White cell count $14.5 \times 10^9/L$ (4-11 $\times 10^9$)

Platelets $>450 \times 10^9/L$ (150-400 $\times 10^9$)

Sodium 122 mmol/L (137-144)

Potassium 5.2 mmol/L (3.5-4.9)

Urea 4.6 mmol/L (2.5-7.5)

Creatinine 85 $\mu\text{mol/L}$ (60-110)

Random cortisol 150 nmol/L (200-700)

TSH 1.1 mU/L (0.4-5)

Free T_4 9 pmol/L (10-22)

Prolactin 350 mU/L (<450)

What is the most likely diagnosis?

- 1- Encephalitis
- 2- Meningitis
- 3- Migraine
- 4- Pituitary apoplexy
- 5- Subarachnoid haemorrhage

Answer & Comments

Answer: 4- Pituitary apoplexy

The combination of headache, vomiting, visual disturbance and hormonal dysfunction should lead you to consider a diagnosis of pituitary apoplexy in this case.

Pituitary apoplexy is caused by acute haemorrhage or infarction of the pituitary gland. A pituitary adenoma usually pre-exists.

The visual symptoms include reduced acuity, visual field impairment and ocular motility dysfunction. This is due to involvement of the optic nerve, chiasm and cavernous sinus.

Predisposing factors include bromocriptine, head injury, pregnancy, irradiation and endocrine stimulation tests.

Endocrinologically, the main initial problem is a lack of adrenocorticotrophic hormone (ACTH), which results in a lack of cortisol and the features of an 'Addisonian crisis', i.e. hypotension, hyponatraemia, hyperkalaemia and hypoglycaemia. Subacutely, there can be deficiency in thyroid stimulating hormone (TSH) and gonadotropins (LH and FSH).

The raised white cell count and thrombocytosis here likely reflects a stress response.

Treatment is with urgent steroid replacement and imaging to confirm the diagnosis, with consideration of neurosurgical decompression.

Subarachnoid haemorrhage is a possibility in this case, but the hormone dysfunction makes pituitary apoplexy more likely.

The hormone dysfunction also make the other options less likely. Altered mental status is usually more dominant in cases of encephalitis. Whilst migraine can imitate a number of different conditions, this lady is extremely unwell and migraine does not account for this.

[Q: 4328] OnExamination 2012 -
Neurology

A 45-year-old man presents with headaches and low libido.

He is found to be hypopituitary.

The CT scan shows a pituitary tumour with suprasellar extension.

Which of the following structures is likely to be compressed?

- 1- Abducens nerve
- 2- Hypothalamus
- 3- Oculomotor nerve
- 4- Optic chiasm
- 5- Third ventricle

Answer & Comments

Answer: 4- Optic chiasm

Superior extension of the tumour can lead to compression of firstly the optic apparatus and later the hypothalamus.

Lateral extension of the tumour with compression or invasion of the cavernous sinus can compromise third, fourth, or sixth cranial nerve functions, manifest as diplopia in 5 to 15% of pituitary tumour patients.

The optic chiasm lies 5-10 mm above the diaphragm sellae and anterior to the stalk.

Adenomas larger than 1.5 cm frequently have suprasellar extension, and a magnetic resonance imaging (MRI) scan will show compression and upward displacement of the optic chiasm.

[Q: 4329] OnExamination 2012 -
Neurology

A 75-year-old man is awaiting transurethral resection of the prostate, but is brought into hospital in acute urinary retention.

Which of the following drugs might be responsible?

- 1- Ipratropium bromide inhaler
- 2- Montelukast
- 3- Serevent inhaler
- 4- Sodium chromoglycate
- 5- Theophylline

Answer & Comments

Answer: 1- Ipratropium bromide inhaler

Ipratropium bromide acts as an antimuscarinic bronchodilator and has traditionally been regarded as more effective in relieving bronchoconstriction associated with chronic bronchitis.

Side effects are rare and it does not increase sputum viscosity or affect the mucociliary clearance of sputum.

Reported side effects are dry mouth, blurred vision, constipation and urinary retention.

The nebulised drug has occasionally been reported to leak around the mask and precipitate acute angle closure glaucoma in susceptible patients.

[Q: 4330] OnExamination 2012 -
Neurology

A 42-year-old male with a 15 year history of type 1 diabetes presents with a two month history of deteriorating pain and stiffness of the right shoulder.

On examination he has painful limitation of internal rotation and can abduct the right arm to only 90 degrees. Flexion is relatively unimpaired. There is some weakness of movement of that shoulder with slight wasting of shoulder muscles. He has some reduced vibration sensation in both hands.

Which of the following is the most likely diagnosis?

- 1- Adhesive capsulitis
- 2- Brachial plexopathy

- 3- Calcium pyrophosphate arthropathy
- 4- Diabetic arthropathy
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 1- Adhesive capsulitis

This patient has typical features of a frozen shoulder and this is typified by the reduced internal rotation and abduction of the shoulder. Slight wasting due to pain and reduced use of the shoulder muscles is expected.

Brachial plexopathy is associated with involvement of the brachial plexus with associated specific dermatomal loss of sensation (not the peripheral neuropathy associated with diabetes as in this case) as well as specific loss of strength (not often the shoulder) such as wrist drop, ulna nerve palsy, etc.

[Q: 4331] OnExamination 2012 - Neurology

A 17-year-old female presents with three headaches over a six month period.

She describes the headaches as severe, right-sided and lasting for twelve hours and associated with nausea and photophobia. Each is preceded by spots before her eyes.

What is the most appropriate initial treatment for this patient?

- 1- Diclofenac at the onset of the next attack
- 2- Ergotamine suppository at the onset of the next attack
- 3- Paracetamol plus metoclopramide at the onset of the next attack
- 4- Prophylaxis with propranolol
- 5- Sumatriptan at the onset of the next attack

Answer & Comments

Answer: 3- Paracetamol plus metoclopramide at the onset of the next attack

First line treatment of acute migraine consists of simple analgesic (either soluble paracetamol or aspirin) and an antiemetic (usually domperidone or metoclopramide).

Second line treatment includes the use of non-steroidal-anti-inflammatory drugs such as diclofenac.

If the above measurements fail to alleviate the attacks, then triptan therapy (for example, sumatriptan) is indicated.

It is important for patients to take the treatment as early as possible.

Long term prophylaxis with drugs (for example, propranolol) is only indicated if the attacks are frequent (more than two a month).

[Q: 4332] OnExamination 2012 - Neurology

A 28-year-old shop worker is referred with a three month history of recurrent episodes of disorientation and confusion.

Her boyfriend has found her wandering around the house on several occasions, apparently with no idea of where she is or how she got there. Her mood has been very low, with frequent emotional outbursts, and she has considered leaving her job because of problems with working the computer and managing customers' queries. Her boyfriend feels her condition is significantly worsening.

Physical examination is normal, apart from recurrent, asymmetrical, jerks in all four limbs.

Which of the following investigations is likely to be most useful in reaching a diagnosis?

- 1- Chest x ray
- 2- CT head
- 3- EEG

- 4- Liver function tests
- 5- Visual evoked potentials

Answer & Comments

Answer: 3- EEG

This kind of rapid cognitive decline in a young person with myoclonus is strongly suggestive of Creutzfeldt-Jakob disease (CJD).

A definitive diagnosis of any form of CJD requires pathological examination of brain tissue, which is usually only done post-mortem. During life, investigations are undertaken for two reasons: to exclude other possible diagnoses, and to support the diagnosis of CJD. Supportive investigations are EEG, CSF examination and MRI.

The EEG in sporadic CJD may show significant abnormalities involving deep brain areas such as the thalami. The normal rhythms are gradually lost. Initially the changes are diffuse, and non-specific, developing into generalised bi- or triphasic periodic sharp wave complexes with a frequency of 1-2 per second. High voltage sharp waves may be synchronous with myoclonic jerks. In an appropriate clinical context, this EEG pattern is strongly suggestive of a diagnosis of CJD.

Neither CSF examination nor MRI are options here, but both can also give supportive information.

The CSF typically contains no inflammatory cells, but the total protein content may be raised. Analysis for brain specific proteins, particularly 14-3-3, is supportive in the right clinical context.

In a proportion of cases, abnormalities of signal in the anterior basal ganglia (caudate/putamen, and sometimes the cortex) can be seen on MRI, which can also support the diagnosis.

Chest x ray and liver function tests may help to exclude other diagnoses, but do not give supportive information for CJD.

Visual evoked potentials may be altered in CJD, but no specific pattern has yet been identified to support the diagnosis.

CT head generally demonstrates brain atrophy in CJD, but this is not a specific finding and is therefore less useful than an EEG.

[Q: 4333] OnExamination 2012 - Neurology

A 79-year-old male is admitted with acute confusion and is agitated and aggressive to staff.

His relatives who accompany him assert that he had been entirely self-caring, does not drink alcohol and was taking no previous medication. He was diagnosed with a urinary tract infection and commenced antibiotics but remained agitated and distressed.

Which one of the following treatments is the most appropriate for his agitation?

- 1- Chlorpromazine
- 2- Diazepam
- 3- Quetiapine
- 4- Temazepam
- 5- Trazodone

Answer & Comments

Answer: 3- Quetiapine

Unfortunately all antipsychotics appear to increase the risk of death in patients with dementia. Haloperidol, olanzapine and risperidone may also increase the risk of cerebrovascular events. Olanzapine and risperidone have been shown to increase risk of somnolence, hostility, confusion, fever, abnormal gait, urinary incontinence, asthenia and peripheral oedema. 50% of patients with dementia with Lewy bodies have marked

sensitivity to antipsychotics, with associated raised mortality. Antipsychotics are therefore only indicated in specific situations.

However, in patients with clinically significant agitation, there is evidence that both antipsychotics and benzodiazepines produce benefits that outweigh the risks. Current evidence suggests that the best agent for acute agitation in an elderly patient such as this is quetiapine administered either intramuscularly (IM) or orally.

Benzodiazepines are associated with increased risk of falls, sedation and cognitive impairment and are therefore second line. Lorazepam is the benzodiazepine of choice. Temazepam has a delayed onset of action and is therefore not ideal for this patient, whilst oral diazepam also has too long a duration of action to be of any use as an acute sedative in the elderly.

Trazodone, an anti-depressant, is useful orally as a chronic anxiolytic. Its onset of action is too long to be used acutely.

[Q: 4334] OnExamination 2012 - Neurology

A 50-year-old man presents with tingling in the left upper limb. The pain originated in the neck and radiated down the left arm. He proceeded to have numbness and paraesthesia in the left lower limb.

On examination he had restriction of neck movements and there was a mild wasting to be noted in the left biceps. There was inversion of the supinator and biceps jerks. His knee jerk and ankle jerk were hyperreactive and he has a positive extensor plantar response.

He then developed paraesthesia and numbness of the right lower limb. A diagnosis of cord compression was made and he underwent a surgical decompression.

Post surgery was complicated by septicaemia and urinary tract infection and he remained in

bed for four days. He subsequently developed inability to dorsiflex his right foot and right big toe. There was numbness on the outside of the foot and there was decreased eversion, but inversion was normal. His reflexes remained as before.

What is the cause of the problem?

- 1- Common peroneal nerve palsy
- 2- L4 root lesion
- 3- Recurrence of the original cord compression
- 4- Sciatic nerve palsy
- 5- Spinal cord infarction

Answer & Comments

Answer: 1- Common peroneal nerve palsy

The commonest cause of acute foot drop after prolonged bed rest is entrapment common peroneal neuropathy at the neck of fibula.

Typically there is weakness of ankle dorsiflexion, eversion, diminished sensation of the lateral aspect of leg and dorsum of foot.

The ankle reflex remains intact.

[Q: 4335] OnExamination 2012 - Neurology

A 75-year-old woman presents with acute monocular visual loss.

Fundoscopy reveals a swollen pale optic disc in the affected eye.

What is the most likely diagnosis?

- 1- Central retinal vein occlusion
- 2- Closed angle glaucoma
- 3- Giant cell arteritis
- 4- Optic neuritis
- 5- Raised intracranial pressure

Answer & Comments

Answer: 3- Giant cell arteritis

The presence of a swollen optic disc suggests ischaemic optic neuropathy.

In elderly people giant cell arteritis is a common presentation of acute monocular visual loss.

Optic neuritis is very rare in people over the age of 50.

You would expect bilateral swollen optic discs in raised intracranial pressure.

In central retinal vein occlusion you would expect diffuse retinal haemorrhages.

[Q: 4336] OnExamination 2012 - Neurology

Gaucher's disease is associated with the deficiency of which of the following?

- 1- Arylsulphatase-A
- 2- B-Glucosidase
- 3- Hexosaminidase A
- 4- Iduronidase
- 5- Sphingomyelinase

Answer & Comments

Answer: 2- B-Glucosidase

Hexosaminidase A deficiency is associated with Tay-Sachs disease.

Sphingomyelinase deficiency is associated with Niemann-Pick disease.

Arylsulphatase-A deficiency is associated with metachromatic leucodystrophy.

Iduronidase deficiency is associated with Hurler's syndrome.

[Q: 4337] OnExamination 2012 - Neurology

A 21-year-old female presented with a

sudden onset of left sided head and neck pain.

Twenty four hours later she presents with sudden onset of right hemiparesis, facial weakness and homonymous hemianopia and left Horner's syndrome.

A CT brain showed a left middle cerebral artery territory infarction.

Which of the following is the most likely diagnosis?

- 1- Antiphospholipid syndrome
- 2- Cardiac embolism
- 3- Left carotid artery dissection
- 4- Migraine
- 5- Systemic vasculitis

Answer & Comments

Answer: 3- Left carotid artery dissection

The two commonest causes of young onset stroke (less than 40 years) are cardioembolism and carotid artery dissection.

Carotid artery dissection is either spontaneous or traumatic. Facial/head/neck pain and Horner's syndrome are characteristic features.

Migrainous stroke usually affects the posterior circulation (posterior cerebral artery territory is the commonest).

[Q: 4338] OnExamination 2012 - Neurology

Chronic subdural haematoma in a 75-year-old man is not associated with the presence of which of the following?

- 1- Bilateral papilloedema
- 2- Hemiparesis
- 3- Fluctuating level of consciousness
- 4- Impaired cognitive function
- 5- Internuclear ophthalmoplegia

Answer & Comments

Answer: 5- Internuclear ophthalmoplegia

Chronic subdural haematoma is classically associated with fluctuating conscious level and cognitive function.

Bilateral papilloedema may occur with raised intracranial pressure.

Bilateral internuclear ophthalmoplegia is associated with multiple sclerosis and unilateral lesions of medial longitudinal fasciculus may occur with small brain stem infarcts.

Unequal pupils are associated with rapid transtentorial coning in extradural haemorrhage leading to ipsilateral dilated pupil followed by bilateral fixed dilated pupils.

[Q: 4339] OnExamination 2012 - Neurology

A 47-year-old man presents with memory impairment worsening over nine months.

He has jerking movements of his limbs and biphasic high-amplitude sharp waves on EEG.

Which diagnosis is most likely?

- 1- Alzheimer's disease
- 2- Creutzfeld-Jakob disease
- 3- Multi-infarct dementia
- 4- Normal pressure hydrocephalus
- 5- Pick's disease

Answer & Comments

Answer: 2- Creutzfeld-Jakob disease

Biphasic high-amplitude sharp waves are characteristic of Creutzfeld-Jacob disease.

However the young age, rapid onset and myoclonus make this diagnosis the most likely.

[Q: 4340] OnExamination 2012 - Neurology

Which of the following will not be affected by a lesion of the facial nerve in the internal auditory meatus?

- 1- Blinking
- 2- Hearing
- 3- Lacrimation
- 4- Sweating over the cheek
- 5- Taste

Answer & Comments

Answer: 4- Sweating over the cheek

The extent of dysfunction depends on the level of injury.

If it is proximal to geniculate ganglion, for example, internal auditory meatus, taste is lost in the anterior 2/3 of tongue. Also secretion from submandibular, sublingual and lacrimal glands is impaired.

Hyperacusis is due to paralysis of stapedius. Orbicularis oculi is affected causing inability to blink/close eyelids.

Sensation over the face is supplied by the trigeminal nerve, and sweat glands are controlled by the sympathetic nervous system, for example, anhidrosis in Horner's syndrome.

[Q: 4341] OnExamination 2012 - Neurology

A 75-year-old man is diagnosed with a Lewy body dementia.

Which one of the following drugs would be contraindicated for this patient?

- 1- Chlormethiazole
- 2- Donepezil
- 3- Haloperidol
- 4- L-Dopa

5- Selegiline

Answer & Comments

Answer: 3- Haloperidol

Diffuse Lewy body disease is the third commonest cause of dementia (after Alzheimer's disease and vascular dementia).

It presents with:

Cognitive impairment

Visual hallucinations

Parkinsonism.

A common manifestation of the disease is severe neuroleptic treatment intolerance which can be fatal.

[Q: 4342] OnExamination 2012 - Medicine

A 22-year-old male nurse presents to the emergency department following a fight in a pub. In self defence, during a messy brawl between patients, he punched a patient in the face and sustained a deep laceration to his knuckle from his assailant's tooth.

After the wound is cleaned and he has received tetanus immunisation, which of the following antibiotic regimes would be most appropriate for this patient?

- 1- Co-amoxiclav oral
- 2- Doxycycline oral
- 3- Flucloxacillin oral
- 4- Penicillin G IM
- 5- Trimethoprim oral

Answer & Comments

Answer: 1- Co-amoxiclav oral

There is little research into this area but human bites are notorious for causing infection.

This type of closed fist injury is very susceptible to deep infection because the tendon can be infected at the point of injury and then, when the hand relaxes, it slips back into its sheath and is impossible to clean fully.

Broad spectrum antibiotics, typically co-amoxiclav, are used.

[Q: 4343] OnExamination 2012 - Medicine

A patient has daytime sleepiness. He wakes up in the morning un-refreshed. He frequently dozes off while watching TV.

He is hypertensive but well controlled with amlodipine 5 mg and ramipril 2.5 mg. He occasionally takes paracetamol for back pain. Neurological examination was normal. His BMI is 45.

His thyroid function tests were normal as well as IGF-1.

Obstructive sleep apnoea (OSA) is suspected.

Which of the following would make OSA more likely?

- 1- Cataplexy
- 2- High Epworth sleepiness score
- 3- Low Epworth sleepiness score
- 4- Low hypocretin levels in CSF
- 5- Witness of snoring during sleep

Answer & Comments

Answer: 2- High Epworth sleepiness score

Epworth sleepiness score consists of questions which are marked out of 24.

Scores greater than 9 raise the suspicion of the possibility of OSA. It should be interpreted in the context of history.

Those with high scores should be referred for further assessment.

[Q: 4344] OnExamination 2012 - Medicine

A 26-year-old man presents with gradual onset of cough and shortness of breath on exertion. He has no medical history of note. He is single and smokes 20/ day.

His O₂ sat is 93% but drops on minimal exertion. Chest examination was unremarkable. A chest x ray is requested.

What is the most likely diagnosis?

- 1- Asthma
- 2- COPD
- 3- Lung abscess
- 4- Pneumocystis carinii pneumonia (PCP)
- 5- Pulmonary embolism

Answer & Comments

Answer: 4- Pneumocystis carinii pneumonia (PCP)

In PCP there is O₂ desaturation after minimal exertion.

Chest x ray classically shows bilateral perihilar shadowing.

Smoking was a distractor.

[Q: 4345] OnExamination 2012 - Medicine

An 83-year-old man is admitted with light-headedness and bradycardia.

An ECG shows sinus bradycardia with a PR interval of 0.18s. You note that he is taking labetalol. On further questioning he tells you that he has been taking labetalol at the same dose for years.

His estimated glomerular filtration rate (eGFR) is 60ml/min/1.73m².

Which of the following would most accurately describe the reason for developing bradycardia?

- 1- He has developed age-related sinus node dysfunction
- 2- Increased absorption due to slower gastric emptying
- 3- Labetalol follows zero order kinetics that change with age
- 4- Reduced first pass metabolism
- 5- Reduced glomerular filtration rate and excretion

Answer & Comments

Answer: 4- Reduced first pass metabolism

Answer D is correct because drugs like labetalol undergo extensive first pass metabolism in the liver. Liver mass and blood flow decrease with age which in turn increases

the bioavailability of drugs like labetalol giving rise to greater therapeutic effect.

The patient may have taken the same dose of drugs for years, but as the liver ages the bioavailability of the drugs increases as described above.

[Q: 4346] OnExamination 2012 - Medicine

A 47-year-old man with confusion is brought into the emergency department via ambulance.

He has a history of alcohol abuse and is currently living in a homeless shelter. On questioning he reports feeling generally unwell for several months with malaise and weight loss. He has recently complained of a headache to workers at the house, and has been acting strangely over the last few days.

He was treated for tuberculosis (TB) two years ago, but was non-compliant with medication. He is investigated and diagnosed with cerebral tuberculosis. He is commenced on rifampicin, pyrazinamide, ethambutol and isoniazid. He is also started on steroid therapy.

For how long should treatment be continued in total?

- 1- 2 months
- 2- 4 months
- 3- 6 months
- 4- 8 months
- 5- 12 months

Answer & Comments

Answer: 5- 12 months

Worldwide TB affects 10 million people and causes two million deaths.

In developed countries it is relatively uncommon. Those who are elderly, malnourished or immunocompromised (HIV,

diabetes, alcoholism, corticosteroid therapy) are susceptible.

Uncomplicated pulmonary TB is treated for a total of six months, with a three or four drug regime continued for two months followed by using rifampicin and isoniazid for the remaining four months.

In meningeal or cerebral TB, a four drug regime is continued for 12 months (use of steroids is also recommended) to ensure adequate brain penetration and to prevent cranial nerve compression by meningeal scarring. Current NICE guidelines recommend a treatment regimen of isoniazid, pyrazinamide, rifampicin and a fourth drug (for example, ethambutol) for the first 2 months, followed by isoniazid and rifampicin 10 months. In addition a glucocorticoid (equivalent to prednisolone 20-40 mg) is recommended for the first 2-3 weeks, then with gradual reduction.

[Q: 4347] OnExamination 2012 - Medicine

A 25-year-old chef undergoes a Mantoux test as a colleague has just tested positive for sputum positive tuberculosis.

Which of the following response would indicate she has been infected with the disease?

- 1- 3mm
- 2- 6mm
- 3- 9mm
- 4- 12mm
- 5- 18mm

Answer & Comments

Answer: 5- 18mm

The Mantoux test replaced the Heaf test in 2005 in the UK. One of its uses is for patients who have had close contact with a person known to have tuberculosis.

The injection site should be reviewed 48-72 hours following intradermal inoculation of tuberculin. The left forearm is typically used. Only the induration, not surrounding erythema, is used in the measurement and the longest diameter is measured in millimetres:

Less than 6mm: negative test, previously unvaccinated individuals can be given the BCG (within three months) provided there are no contraindications

More than 6mm but less than 15mm: hypersensitive to tuberculin protein (may be due to previous TB infection, BCG, or atypical mycobacteria). Patients are not given the BCG if part of an immunisation programme. However, in other contexts (e.g. immigrant screening and contact tracing), further investigation should and follow-up may be indicated.

More than 15mm: strongly hypertensive to tuberculin, suggestive of TB infection. Patients should be referred for further investigation and treatment

The reaction to tuberculin protein may be suppressed by viral infections, live viral vaccines, sarcoidosis, corticosteroids, immunosuppression, severe tuberculous disease and poor nutrition.

[Q: 4348] OnExamination 2012 - Medicine

A 69-year-old woman presents to the medical admission unit with a two month history of increasing lethargy and confusion. She also complains of headaches, and on the day of admission her husband reports her speech has become slurred.

An urgent CT head is performed, and is reported as showing several cerebral metastases with surrounding oedema. She is started on high dose dexamethasone with some improvement in her symptoms.

Which of the following investigations has the greatest chance of identifying the primary tumour?

- 1- Chest x ray
- 2- Cystoscopy
- 3- Mammography of the breast
- 4- Sigmoidoscopy
- 5- Ultrasound of the kidneys

Answer & Comments

Answer: 1- Chest x ray

Approximately 20% of people who die from cancer have brain metastases. These can be solitary or multiple.

The most common sites that metastasise to the brain are; lung (44%), breast (10%), kidney (7%), gastrointestinal tract (6%) and melanoma (skin - 3%).

Therefore a chest x ray would be the initial investigation of choice, with the greatest chance of finding the primary.

[Q: 4349] OnExamination 2012 - Medicine

A 29-year-old junior doctor comes to the Emergency department complaining of a severe headache and neck stiffness. He has had mild diarrhoea over the past few days, and some coryzal symptoms.

On examination his BP is 155/82 mmHg, his pulse is 85 and regular and his temperature is 37.8°. He has signs consistent with severe meningism but there are no skin rashes or other signs of vasculitis.

Investigations show:

Haemoglobin 13.8 g/dl(13.5-17.7)

White cells $8.9 \times 10^9/L$ (4-11)

Platelet $183 \times 10^9/L$ (150-400)

Sodium 141 mmol/(135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 92 micromol/l (79-118)

Lumbar puncture - lymphocytosis, slightly raised protein, normal glucose.

Which of the following is the most likely diagnosis?

- 1- Cytomegalovirus meningitis
- 2- Enterovirus meningitis
- 3- Herpes simplex encephalitis
- 4- Meningococcal meningitis
- 5- Subarachnoid haemorrhage

Answer & Comments

Answer: 2- Enterovirus meningitis

The answer is option B, Enterovirus meningitis.

Enterovirus is the commonest cause of viral meningitis in the adult population. The coryzal symptoms coupled with a mild diarrhoeal illness fit with this picture, as do the lumbar puncture findings.

Management of viral meningitis is conservative, with adequate hydration and analgesia.

[Q: 4350] OnExamination 2012 - Medicine

A 36-year-old single woman with a history of asthma comes to the clinic complaining of symptoms of indigestion. She uses a steroid inhaler and on examination of her oropharynx you can see obvious evidence of candidiasis. You send her for an endoscopy, which unfortunately reveals extensive oesophageal candidiasis.

Which of the following tests would be most important to consider in this patient?

- 1- CD4 count
- 2- Complement testing
- 3- Fasting blood glucose
- 4- HIV antibody testing

5- Immunoglobulin testing

Answer & Comments

Answer: 4- HIV antibody testing

The answer is D, HIV antibody testing.

Whilst candidiasis affecting the oropharynx may be a result of poor inhaler technique and deposition of steroid powder within the mouth, it does not usually result in oesophageal candidiasis.

The other possible cause of recurrent oral and genital candida infection is diabetes mellitus, although again this would not normally lead to oesophageal disease.

In the case of this patient, immunocompromise should be suspected and HIV considered, with appropriate pre-test counselling.

[Q: 4351] OnExamination 2012 - Medicine

A 52-year-old man has a history of hypertension, managed with amlodipine and indapamide. His GP recently tried to commence ramipril, but had to curtail this as his creatinine rose from 129 to 194 after one week of therapy.

He smokes 20 cigarettes per day and is a vasculopath having suffered a transient ischaemic attack (TIA) one year earlier.

On examination in the clinic his BP is 155/92 mmHg, pulse is regular at 80 and a left carotid bruit is audible.

Investigations show:

Haemoglobin 12.0 g/dl(13.5-17.7)

White cell count $6.0 \times 10^9/L$ (4-11)

Platelets $288 \times 10^9/L$ (150-400)

Serum sodium 140 mmol/l (135-146)

Serum potassium 4.0 mmol/l (3.5-5)

Creatinine 122 $\mu\text{mol/l}$ (79-118)

Ultrasound scan: Right kidney smaller than the left

Renal MRA: Suggestive of 80% right renal artery stenosis

Which of the following is the most appropriate next step in his management?

- 1- Add bisoprolol to his anti-hypertensive regimen
- 2- Re-introduce low dose ramipril to his regimen
- 3- Refer for urgent angioplasty and stenting
- 4- Refer for vascular surgery
- 5- Trial valsartan as an alternative to ACE inhibition

Answer & Comments

Answer: 1- Add bisoprolol to his anti-hypertensive regimen

There is considerable debate about the success of angioplasty/stenting or vascular surgery in patients with atherosclerotic renal artery stenosis and difficult to manage hypertension. The most recent study by Bax et al showed no difference in outcomes between those patients managed with medical therapy versus stenting.

Other studies suggest that complications of stenting or angioplasty outweigh any benefits versus medical therapy.

There is no evidence to support re-introducing ACE inhibition or substituting an angiotensin receptor blocker (ARB) with respect to potential outcomes. As such, in the first instance, response to increased medical therapy for blood pressure should be assessed.

Reference:

Bax L, Woittiez AJ, Kouwenberg HJ et al. (2009) Stent placement in patients with atherosclerotic renal artery stenosis and impaired renal function: a randomized trial. *Ann Intern Med.* 150(12): 840-848

[Q: 4352] OnExamination 2012 - Medicine

An 86-year-old lady is admitted with parkinsonism.

Exposure to which of the following drugs is the most likely cause?

- 1- Buprenorphine
- 2- Cyclizine
- 3- Metoclopramide
- 4- Phenytoin
- 5- Trimethoprim

Answer & Comments

Answer: 3- Metoclopramide

Metoclopramide is a dopamine receptor antagonist that can induce parkinsonism. It can also worsen control in patients with idiopathic Parkinson's disease to its antagonistic effect on dopamine receptors.

Answer A is incorrect because buprenorphine is an opioid agonist and does not cause parkinsonism.

Answer B should not be selected, because it is very rare for cyclizine to induce parkinsonism. Cyclizine is a histamine receptor antagonist.

Of the options given, metoclopramide is far more likely to cause extrapyramidal side effects.

Answer D should not be selected because there have been only two case reports of phenytoin-induced parkinsonism that resolved after discontinuation of phenytoin.

The most likely cause is metoclopramide (option C).

Answer E is incorrect because trimethoprim does not cause extrapyramidal side effects.

[Q: 4353] OnExamination 2012 - Medicine

A 17-year-old girl, who works at a petting zoo, presents with a headache and vomiting to the emergency department. Apparently she suffered a severe diarrhoeal illness which began a few days ago, and she is now passing diarrhoea mixed with blood and mucus.

She has no past history of note, and her only medication is the oral contraceptive pill.

On examination she looks unwell, her BP is 155/92 mmHg and she is pyrexial at 38.2°C. Her abdomen is soft and diffusely tender with very active bowel sounds.

Investigations reveal:

Haemoglobin 10.0 g/dl(11.5-16.5)

White cell count $11.6 \times 10^9/L$ (4-11)

Platelets $50 \times 10^9/L$ (150-400)

Serum Sodium 139 mmol/l (135-146)

Serum potassium 6.0 mmol/l (3.5-5)

Creatinine 295 $\mu\text{mol/l}$ (79-118)

What do expect to find on the blood film?

- 1- Decreased reticulocytes
- 2- Increased lymphocytes
- 3- Increased ghost cells
- 4- Increased schistocytes
- 5- Increased spherocytes

Answer & Comments

Answer: 4- Increased schistocytes

This patient has a history consistent with Escherichia coli 157 infection, and a picture of haemolytic uraemic syndrome (HUS).

The hallmark of HUS is the appearance of schistocytes (fragmented, deformed, irregular, or helmet shaped red cells) on the blood film. Despite the low platelet count, petechiae and purpura are rarely seen, although GI bleeding is often noted.

Treatment is generally supportive. Non-steroidal anti-inflammatory drugs and anti-diarrhoeals should be avoided, and there is no evidence for the use of antibiotics in the condition.

[Q: 4354] OnExamination 2012 - Medicine

A 55-year-old gentleman is suffering with erectile dysfunction.

He has a past medical history of type 2 diabetes and angina.

Which of the following medications would be a contraindication to prescribing sildenafil?

- 1- Clopidogrel
- 2- GTN spray used once per month
- 3- Metoprolol
- 4- Nicorandil
- 5- Propranolol

Answer & Comments

Answer: 4- Nicorandil

The phosphodiesterase 5 inhibitors should be avoided in patients taking nitrates or nicorandil. This is due to vasodilatation potentially causing hypotension and precipitating a myocardial event.

The gentleman using a GTN spray less than once per week could be prescribed sildenafil, although it is worth warning him that should he have chest pain requiring the Emergency department after having taken sildenafil, he should warn his health care providers so that they can avoid nitrates whilst treating his symptoms.

Myocardial infarction is a contraindication to the use of sildenafil; however cardiovascular disease (that is, angina) requires cautious prescribing.

Other patients in which PDE5 inhibitors should be used with caution are those with risk of

priapism, such as sickle cell or multiple myeloma.

None of the other drugs, aspirin, clopidogrel, ACE inhibitors and beta blockers are contraindications to the use of sildenafil.

[Q: 4355] OnExamination 2012 - Medicine

You perform a renal function test on a 25-year-old man and an 83-year-old lady.

Both of them have a creatinine level of 90 mmol/l. You note, however, that the estimated glomerular filtration rate (eGFR) for the young man is 95 ml/min/1.73m² and that the eGFR for the elderly lady is 55 ml/min/1.73m².

Which of the following is the most likely explanation?

- 1- Age related change to the medullary vasculature
- 2- Age related muscle loss in the elderly lady
- 3- Increased glomerular filtration rate in the young man
- 4- Increased muscle mass in the young man
- 5- Reduced blood flow in the afferent arterioles of the cortex in the elderly lady

Answer & Comments

Answer: 2- Age related muscle loss in the elderly lady

Answer B is correct because there is a decline in glomerular filtration rate and plasma flow rate associated with age.

The creatinine level in the plasma does not increase because there is age related muscle loss. A 'normal' creatinine in an elderly patient is thus not indicative of normal renal function and is a poor marker to establish whether an elderly patient has renal impairment. It is much more accurate to use estimated glomerular filtration rate (eGFR).

Answer A is incorrect because there is no change to medullary vasculature associated with ageing.

Answer C is incorrect because this man has a normal glomerular filtration rate.

Answer D is incorrect because if there was increased muscle mass in the young man the creatinine level could be normal or even high. This would however not explain why the elderly lady has a lower eGFR and 'normal' creatinine.

Answer E should not be selected because although there is reduced blood flow in the afferent arterioles of the cortex associated with ageing, this would not explain the relatively 'normal' level of creatinine in the elderly lady.

[Q: 4356] OnExamination 2012 - Medicine

An 88-year-old woman is admitted with swollen legs and increased abdominal swelling. She is commenced on intravenous furosemide and responds well.

You note that she has been on oral furosemide at home.

Which of the following best explains the reason for the response to intravenous drugs?

- 1- Decreased protein binding of furosemide
- 2- Increased bioavailability
- 3- Increased effect on the loop of Henle
- 4- Increased first pass metabolism
- 5- Increased plasma volume

Answer & Comments

Answer: 2- Increased bioavailability

Answer B is correct. This lady has a lot of gut oedema secondary to right heart failure which would reduce the absorption of oral furosemide. Intravenous furosemide would

have a much better bioavailability and thus therapeutic effect.

Answer A is not correct. Protein binding of drugs may be reduced in elderly patients. This may be due to malnutrition. In this case scenario, however, furosemide is poorly absorbed from the gut.

Answer C should not be selected. Intravenous furosemide would have a more pronounced effect on the loop of Henle due to increased bioavailability of the drug when given intravenously due to poor absorption secondary to gut oedema as stated above.

Answer D should not be selected. Furosemide undergoes about 40% first pass metabolism in the gut and the kidney. First pass metabolism may be reduced as a result of liver congestion.

Answer E should not be selected because the increased plasma volume is likely secondary to heart failure itself.

[Q: 4357] OnExamination 2012 - Medicine

An 86-year-old man sees you in clinic.

He is a keen marathon runner and tells you that he gets breathless much earlier on in a race than he did 10 years ago.

Which physiological change associated with age would be the most likely cause for his symptoms?

- 1- Diastolic dysfunction and reduced stroke volume
- 2- Higher systolic arterial pressure and increased impedance to left ventricular ejection
- 3- Increased sino-atrial conduction time
- 4- Left ventricular hypertrophy
- 5- Reduced tachycardic response

Answer & Comments

Answer: 5- Reduced tachycardic response

Answer E is correct. There is a reduced tachycardic response during exercise associated with age. The heart has to compensate by increasing stroke volume and failure to do so will reduce aerobic capacity. Some fit, healthy elderly men can compensate for this by increasing left ventricular filling and thus stroke volume (Starling's law).

Answers A,B, C and D are all physiological changes associated with age. They occur, irrespective of whether a patient exercises or not.

The symptoms that this patient describes are during exercise and failure of the heart to respond appropriately to exercise by increasing the heart rate will lead to dyspnoea.

[Q: 4358] OnExamination 2012 - Medicine

A 68-year-old man with a 45/year pack history is referred by his GP to the respiratory clinic with increasing breathlessness over the last 12 months.

He has a cough productive of clear sputum, which appears to be present most days. He has no weight loss and no history of haemoptysis.

His spirometry results show FEV₁/FVC 0.65 and FEV₁ (% predicted) 71%.

Based on the latest NICE guidelines, what (if any) is the severity of this man's airflow obstruction?

- 1- Mild
- 2- Moderate
- 3- No airflow obstruction
- 4- Severe
- 5- Very severe

Answer & Comments

Answer: 2- Moderate

NICE have recently (2010) produced a clinical guideline as a tool to assess airflow obstruction.

There have been some alterations to the previous classification of airflow obstruction, based on other the American Thoracic Society, GOLD and European Respiratory Society standards.

Below are the new classifications:

Mild - FEV₁ predicted greater than 80%

Moderate - FEV₁ predicted 50-79%

Severe - FEV₁ predicted 30-49%

Very severe - FEV₁ predicted less than 30%.

NICE guidelines

[Q: 4359] OnExamination 2012 - Medicine

A 31-year-old motorcyclist becomes confused and dyspnoeic on the orthopaedic ward, 24 hours after fracturing his right femur in an accident.

Which of the following skin lesions may be found on examination?

- 1- Multiple petechiae in both axilla
- 2- Palpable purpura on buttocks and legs
- 3- Target lesions on his chest
- 4- Tender red nodules on his shins
- 5- Vesicular lesions on his torso

Answer & Comments

Answer: 1- Multiple petechiae in both axilla

The appearance of multiple petechiae in the distribution of the axilla or upper body is characteristic of a fat embolism.

Unlike emboli that arise from a thrombus, fat emboli are small and multiple producing widespread effects. They may occur one to three days following a fracture and are more

common in closed fractures on the long bones or pelvis.

The clinical features of fat emboli are predominately

Pulmonary (shortness of breath, hypoxia)

Neurological (confusion and agitation)

Dermatological (petechiae) and

Haematological (thrombocytopenia, anaemia).

The petechial rash is pathognomonic of this syndrome, but occurs in only 30-50% of cases.

[Q: 4360] OnExamination 2012 - Medicine

A 18-year-old student presents to the student health service with frank haematuria that began some 48 hours after an upper respiratory tract infection.

On examination he is afebrile, BP is 110/72 mmHg and pulse is 70. His chest is clear and his abdomen is soft and non-tender.

Investigations reveal:

Haemoglobin 14.0 g/dl (13.5-17.7)

White cell count $8.0 \times 10^9/L$ (4-11)

Platelets $248 \times 10^9/L$ (150-400)

Serum sodium 138 mmol/l (135-146)

Serum potassium 4.3 mmol/l (3.5-5)

Creatinine 85 $\mu\text{mol/l}$ (79-118)

Urine blood +++

Which of the following is the most appropriate way to manage him?

- 1- ACE inhibitor titrated to maximal tolerated dose
- 2- ACE inhibitor titrated to maximal tolerated dose and ARB in combination
- 3- Methylprednisolone and cyclophosphamide
- 4- Observation
- 5- Prednisolone 60 mg/day

Answer & Comments

Answer: 4- Observation

This patient almost certainly has IgA nephropathy, given his presentation with frank haematuria occurring in such close proximity to a recent upper respiratory tract infection.

The findings including normal blood pressure, normal creatinine and haematuria without proteinuria point towards a benign prognosis and for this reason he only requires regular monitoring rather than intervention with immunosuppressive agents.

Treatment with corticosteroids is usually reserved for those patients with hypertension and a rising creatinine.

Where there is significant hypertension +/- proteinuria, then ACE inhibitors are the first choice antihypertensive agent.

Post-streptococcus glomerulonephritis usually occurs one to three weeks after initial infection.

[Q: 4361] OnExamination 2012 - Medicine

A 49-year-old woman comes to the clinic complaining of rapidly worsening lethargy and nausea. Over the past few days she has become increasingly unwell and is now barely able to get out of the house.

Other symptoms of note include progressive shortness of breath and a cough productive of blood stained sputum. Her only consultations with the doctor over the past six months have been about the shape of her nose; she has suffered some collapse of her nasal bridge and is considering plastic surgery.

On examination you notice collapse of the bridge of her nose, and nasal congestion when she speaks. Her BP is elevated at 155/95 mmHg. You can hear crepitations on auscultation of the chest.

Investigations show:

Haemoglobin 12.0 g/dl(11.5-16.5)

White cell count $11.6 \times 10^9/L$ (4-11)

Platelets $202 \times 10^9/L$ (150-400)

Serum Sodium 139 mmol/l (135-146)

Serum Potassium 5.8 mmol/l (3.5-5)

Creatinine 285 micromol/l (79-118)

CXR Patchy interstitial shadowing

C-ANCA Positive

Which of the following is the most appropriate treatment?

- 1- Infliximab
- 2- Methylprednisolone and azathioprine
- 3- Methylprednisolone and cyclophosphamide
- 4- Methylprednisolone and methotrexate
- 5- Prednisolone

Answer & Comments

Answer: 3- Methylprednisolone and cyclophosphamide

Methylprednisolone and cyclophosphamide is the treatment of choice for induction of remission in Wegener's granulomatosis, the obvious diagnosis here.

Evidence from controlled trials suggests that once remission is achieved azathioprine or methotrexate may be reasonable alternatives to cyclophosphamide.

In refractory Wegener's, both infliximab and rituximab have shown some degree of promise.

Prognosis is dependent on prompt diagnosis and early intervention with immunosuppressive therapies, with evidence suggesting that time to diagnosis has shortened over the past few years.

[Q: 4362] OnExamination 2012 - Medicine

A 67-year-old man with chronic renal failure, who uses peritoneal dialysis, presents to the renal ward with a cloudy bag. This is his first episode of continuous ambulatory peritoneal dialysis (CAPD) peritonitis in over two years of dialysing.

He has type 1 diabetes, which precipitated his renal impairment. On examination, he is pyrexial at 38.2°C. His abdomen is diffusely tender, although he has bowel sounds on auscultation.

Investigations showed:

Haemoglobin 10.2 g/dl(13.5-17.7)

White cell count $13.6 \times 10^9/L$ (4-11)

Platelets $270 \times 10^9/L$ (150-400)

Serum Sodium 138 mmol/l (135-146)

Serum Potassium 4.3 mmol/l (3.5-5)

Creatinine 346 $\mu\text{mol/l}$ (79-118)

Dialysis fluid >100 white cells per mm³

Which of the following is the most likely infecting organism?

- 1- B. fragilis
- 2- Bacteroides spp
- 3- P. aeruginosa
- 4- S. aureus
- 5- S. pyogenes

Answer & Comments

Answer: 4- S. aureus

S. aureus and S. epidermidis are the two commonest pathogens identified in cases of CAPD peritonitis.

Various treatment regimes exist, but the majority involve intraperitoneal vancomycin and an oral quinolone. Once culture results are received, the regime can then be tailored appropriately.

The key to avoiding long term complications of CAPD peritonitis is prompt intervention to avoid chronic colonisation of the CAPD catheter and adhesion formation, which prevents adequate fluid exchange.

[Q: 4363] OnExamination 2012 - Medicine

A student from the Indian subcontinent has recently been diagnosed with sputum positive tuberculosis (TB).

He lives on the university campus in a shared flat. His housemates are contacted by public health and requested to undergo screening.

Which of the following investigations is most commonly used in this instance?

- 1- Blood test
- 2- Chest x ray
- 3- Heaf test
- 4- Mantoux test
- 5- Microbiology (sputum)

Answer & Comments

Answer: 4- Mantoux test

The Mantoux test is the most commonly used screening test for contacts of a patient with recently diagnosed TB. If this suggests a risk of infection, then a chest x ray is performed and appropriate follow up arranged.

Heaf tests are now less commonly used as a screening test.

Blood tests may indicate anaemia, hyponatraemia or hypercalcaemia, which are sometimes seen in infection, but would not have a role in screening.

Microbiology - assessing either sputum or bronchial washings for acid-fast bacilli - would not be routinely used in asymptomatic contacts.

[Q: 4364] OnExamination 2012 - Medicine

A 60-year-old Asian man who has lived in the United Kingdom for the past 15 years presents with painless haematuria. He is otherwise well. He is a smoker of 10 cigarettes per day.

Investigations reveal a haemoglobin of 11 g/dl (13-18g/dl). His WBC, ESR, CRP, LFTs, Urea and electrolytes are normal. Urinalysis shows ++ blood and a PA chest x-ray shows small flecks of white opacifications in the upper lobe of the left lung.

What is the most likely diagnosis?

- 1- Bladder carcinoma
- 2- Glomerular disease
- 3- Prostatic carcinoma
- 4- Renal calculi
- 5- Tuberculosis

Answer & Comments

Answer: 1- Bladder carcinoma

The presence of painless haematuria in a male smoker should lead you to consider bladder carcinoma as a diagnosis. The majority of these tumours are transitional cell carcinomas, although they can be squamous carcinomas (associated with a worse prognosis). The usual presentation is with bleeding or urinary tract obstruction (more common with lesions of the renal pelvis and ureter). Several carcinogens including smoking, rubber and analine dye exposure and analgesic nephropathy have been linked with bladder carcinoma. Other risk factors include renal calculi, cystic renal disease, chronic cystitis, Schistosoma haematobium and cyclophosphamide. Treatment is with surgery and radiotherapy, which results in a 5-year survival rate of 50%.

The patient's ethnicity and the chest x ray findings are suggestive of previous TB infection. TB can also affect the urinary tract,

but if that were the diagnosis her you would also expect him to complain of malaise, sweats, weight loss or symptoms of UTI.

Glomerular disease typically results in deranged renal function, and there is often also proteinuria. Prostatic carcinoma usually causes symptoms of urinary tract obstruction prior to haematuria. Renal calculi are painful.

[Q: 4365] OnExamination 2012 - Medicine

A patient was diagnosed with TB and had been on treatment for two months.

He was lost to follow up. Four months later he presented with haemoptysis and fatigue. On examination his temperature was 38.2°. Sputum analysis for acid fast bacilli was positive.

The patient is suspected of having multiple drug resistant tuberculosis (MDR TB).

Which of the following would be the strongest risk factor for MDR TB?

- 1- Age 12-20 years
- 2- Female gender
- 3- Herpes simplex virus
- 4- HIV
- 5- Resident in Manchester

Answer & Comments

Answer: 4- HIV

The risk factors for MDR TB are

History of prior TB drug treatment; prior TB treatment failure

Contact with a known case of drug-resistant TB

Birth in a foreign country, particularly high-incidence countries

HIV infection

Residence in London

Age profile, with highest rates between ages 25 and 44

Male gender.

(NICE guidance CG117)

[Q: 4366] OnExamination 2012 - Medicine

A 47-year-old patient has daytime sleepiness. He wakes up in the morning un-refreshed. He frequently dozes off while watching TV.

He is hypertensive but well controlled with amlodipine 5 mg and ramipril 2.5 mg. He occasionally takes paracetamol for back pain. Neurological examination was normal. His BMI is 45.

He was referred for suspicion of obstructive sleep apnoea (OSA).

Which of the following tests would you request to confirm diagnosis?

- 1- CT chest
- 2- Echocardiogram
- 3- Multiple sleep latency test
- 4- Polysomnography
- 5- Thyroid function tests

Answer & Comments

Answer: 4- Polysomnography

It is important to be aware of the diagnostic tests for various respiratory problems.

Polysomnography or sleep studies will reveal periods of apnoea during sleep.

Hypothyroidism can be associated with OSA but is not diagnostic.

CT chest and echo are not helpful in making the diagnosis.

[Q: 4367] OnExamination 2012 -
Medicine

A 32-year-old man presents with fever, shortness of breath and productive cough for five weeks.

Prior to that he was fit and well with no respiratory complaints. His only medical history is that he frequently visits his dentist for teeth problems and has been a heavy drinker for a long time.

Three weeks ago he was given antibiotics by his GP with slight improvement but then got worse.

What is the most likely diagnosis?

- 1- Asthma precipitated by pneumonia
- 2- Bronchiectasis
- 3- Empyema
- 4- Lung abscess
- 5- Pulmonary embolism (PE)

Answer & Comments

Answer: 4- Lung abscess

Predisposing factors for lung abscess include dental disease, impaired consciousness, for example, alcohol, post-anaesthesia, bronchial carcinoma and immunosuppression.

Empyema usually does not cause productive cough.

PE is unlikely in this scenario as well as asthma.

Bronchiectasis is a chronic condition and usually there is underlying cause.

[Q: 4368] OnExamination 2012 -
Medicine

An 84-year-old lady is treated for a chest infection in hospital.

On admission her creatinine kinase (CK) level was normal. Three days later she is found to

be in renal failure and has a CK of 8000 mmol/l.

She is taking simvastatin, aspirin, bisoprolol and St John's wort.

Which of the following drugs would be the most likely cause?

- 1- Ciprofloxacin
- 2- Clarithromycin
- 3- Co-amoxiclav
- 4- Doxycycline
- 5- Metronidazole

Answer & Comments

Answer: 2- Clarithromycin

Answer B is correct because there is a significant drug interaction between clarithromycin and simvastatin.

Clarithromycin strongly inhibits CYP3A4 - the enzyme responsible for simvastatin metabolism which can lead to rhabdomyolysis and renal failure.

Macrolide antibiotics and hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors should never be administered together.

Answer A should not be selected. There can be a very rare interaction between ciprofloxacin and simvastatin that can give rise to rhabdomyolysis. The question, however, states the 'most likely' cause for the presentation and that would certainly be answer B.

Answer C is incorrect because it does not inhibit CYP4A4 and does not have a significant interaction with statins.

Answer D should not be selected, because there is no interaction between doxycycline and simvastatin.

Answer E should not be selected. There is a moderate interaction that exists between

simvastatin and metronidazole and patients should be closely monitored for symptoms of peripheral neuropathy.

[Q: 4369] OnExamination 2012 - Medicine

An 82-year-old lady presents with a fall and a Colles' fracture.

She is commenced on alendronate.

Which of the following is the mechanism of the therapeutic effect of this drug?

- 1- Decreasing the effect of endogenous parathyroid hormone
- 2- Improved calcium absorption from the kidney
- 3- Inhibition of osteoblast activity
- 4- Inhibition of osteoclast activity
- 5- Stimulation of osteoblast activity

Answer & Comments

Answer: 4- Inhibition of osteoclast activity

Answer D is correct because alendronate inhibits osteoclast activity and this prevents the breakdown of bone and thus bone loss.

Answers A and B are incorrect because bisphosphonates do not exhibit these therapeutic effects.

Answers C and E are incorrect because alendronate's therapeutic effect is not associated with change in osteoblast activity.

[Q: 4370] OnExamination 2012 - Medicine

A 65-year-old man has recently been diagnosed with non-small cell lung cancer. His management plan is discussed at the regional multi-disciplinary meeting.

Which of the following would not preclude him from being offered surgery?

- 1- FEV₁ 0.4L

- 2- Malignant pleural effusion
- 3- Mediastinal lymphadenopathy
- 4- Sclerotic vertebral lesion on x ray
- 5- Tumour size of 3 cm

Answer & Comments

Answer: 5- Tumour size of 3 cm

A tumour size of greater than 3 cm (providing there is no lymphadenopathy or evidence of distant spread) may still be amenable to surgery as it may fall within stages IB and IIB.

Answers B to D indicate metastatic spread of the disease, and as such surgery would be inappropriate.

A FEV₁ of less than 0.5 is also a contraindication for surgical management.

[Q: 4371] OnExamination 2012 - Medicine

A 50-year-old man is admitted to the hospital with a third attack of renal stones in the last six months.

He suffers from Crohn's disease and has previously had a limited small bowel resection, but his disease is now quiescent. Apparently there is a history of high calcium levels in other blood relatives.

On examination his BP is 115/72 mmHg, his BMI is 19.5, he has a midline scar consistent with a previous laparotomy.

Investigations show:

Haemoglobin 12.0 g/dl (11.5-16.5)

White cell count 6.4 x 10⁹/L (4-11)

Platelets 272 x 10⁹/L (150-400)

Serum Sodium 138 mmol/l (135-146)

Serum Potassium 4.1 mmol/l (3.5-5)

Creatinine 85 µmol/l (79-118)

Calcium 2.89 mmol/l (2.20-2.67)

PTH Upper limit of normal range

Which of the following is the most likely diagnosis?

- 1- Familial hypocalciuric hypercalcaemia
- 2- Primary hyperparathyroidism
- 3- PTHrP levels increased due to underlying malignancy
- 4- Secondary hyperparathyroidism
- 5- Tertiary hyperparathyroidism

Answer & Comments

Answer: 1- Familial hypocalciuric hypercalcaemia

Plasma calcium is tightly regulated by parathyroid hormone (PTH) and vitamin D, which act on the gastrointestinal tract, kidney and bone. PTH releases calcium from bone, and inhibits its excretion from the kidney. Vitamin D promotes calcium absorption from the gastrointestinal tract. Plasma calcium levels are detected by a calcium-sensing receptor on the parathyroid glands.

This gentleman has a raised calcium with an inappropriately high PTH. The remainder of his bloods are normal, with no evidence of renal failure or malabsorption.

Familial hypocalciuric hypercalcaemia is an autosomal dominant condition and is the most likely diagnosis in this case.

The disease most often leads to asymptomatic elevated levels of serum calcium, although some patients with the condition may suffer recurrent episodes of renal stones.

The inherited condition is usually caused by a mutation in the calcium-sensing receptor gene. The perceived lack of calcium levels by the parathyroid leads to resetting of calcium and PTH to higher levels. It does not require any treatment.

Primary hyperparathyroidism is caused by parathyroid adenomas or hyperplasia, which results in raised PTH and subsequently raised

plasma and urinary calcium. Alkaline phosphatase is raised, and serum phosphate is reduced.

Secondary hyperparathyroidism is compensatory hypertrophy of all four glands due to hypocalcaemia (due to chronic kidney disease, or malabsorption). PTH is raised and calcium is low or normal.

Tertiary hyperparathyroidism develops after a prolonged period of secondary hyperparathyroidism. The parathyroid glands become autonomous and both PTH and calcium are raised.

PTH-related protein is responsible for 80% of hypercalcaemia in malignancy, and acts on the same receptors as PTH. It is secreted by squamous cell tumours, breast and renal tumours. Serum calcium is raised, but PTH will be low.

[Q: 4372] OnExamination 2012 - Medicine

A 14-year-old boy presents with a high fever, cervical lymphadenopathy, and pus on the tonsils.

Which of the following statements regarding diagnosis and management is true?

- 1- Amoxicillin may cause an erythematous rash
- 2- Cefotaxime is the treatment of choice
- 3- If his CRP is 40, then Group A streptococcal infection is highly likely
- 4- If urinary red cells are present, then a renal biopsy is indicated
- 5- Tonsillectomy is indicated after the acute infection has settled

Answer & Comments

Answer: 1- Amoxicillin may cause an erythematous rash

Epstein-Barr virus is a common problem in paediatrics, general practice and medical admissions, and unfortunately on clinical appearances it is not possible to distinguish bacterial from viral or throat infections with any degree of reliability.

Urinary red cells may indicate a secondary post-streptococcal glomerulonephritis, but a renal biopsy is unlikely to be indicated.

A Group A streptococcal infection should certainly be considered in this case, and probably covered with oral penicillin-v, but reliable clinical diagnosis is not possible.

If the child has Epstein-Barr virus infection, then the administration of amoxicillin will give an erythematous rash. Non-vomiting patients can be treated with oral penicillin-v.

Cefotaxime, although it would probably be effective, requires IV administrations which does not seem warranted on the information given.

Tonsillectomy should be reserved for those with recurrent tonsillitis not responding to prophylactic antibiotics.

[Q: 4373] OnExamination 2012 - Medicine

A 79-year-old male with critical ischaemia of his foot is awaiting below knee amputation and has lower limb pain.

He is awake and lucid with normal observations.

His full blood count shows:

Haemoglobin 12.0 g/dl(13.0-18.0)

White cell count $14.0 \times 10^9/L$ (4-11)

Platelets $67 \times 10^9/L$ (150-400)

Which of the following is the best option for pain relief?

- 1- Diclofenac 50 mg per oram
- 2- Epidural analgesia
- 3- Femoral nerve block

4- Morphine 10 mg intravenously

5- Tramadol 50 mg per oram

Answer & Comments

Answer: 5- Tramadol 50 mg per oram

Of the options given, tramadol is the best.

In a 79-year-old arteriopath diclofenac is best avoided for fear of renal damage.

Epidural analgesia may confer benefits, especially pre-operatively for below knee amputation, however with platelets of 67 most operators would be reticent to site one.

Femoral nerve block is a relatively simple procedure which may help, but will give incomplete cover and runs the risk of damaging the femoral artery.

10 mg morphine intravenously would be considered hazardous in a 79-year-old (in most people actually).

Tramadol can have unpleasant side effects for the elderly.

[Q: 4374] OnExamination 2012 - Medicine

A 26-year-old patient with known AIDS presents with a history of increasing breathlessness and dry cough. He is investigated by the respiratory team and diagnosed with pneumocystis pneumonia (PCP).

Which of the following features is most accurate regarding PCP?

- 1- Amphotericin is the treatment of choice
- 2- Blood cultures are positive in 1/3rd of cases
- 3- Occurs only in AIDS
- 4- Pleural effusions are most often bilateral
- 5- The lungs are commonly clear on auscultation

Answer & Comments

Answer: 5- The lungs are commonly clear on auscultation

Patients with pneumocystis pneumonia often present with signs and symptoms of respiratory distress, although on examination of the chest there is often no abnormality detected.

Although initially reported as a disease associated with AIDS, PCP can affect any immunocompromised patient including transplant patients.

The trophozoite does not enter the blood stream, and the organism is usually identified in pulmonary secretions.

Co-trimoxazole (Septrin) or pentamidine are the treatments of choice.

[Q: 4375] OnExamination 2012 - Medicine

A 27-year-old lady presents with generalised oedema of five months duration.

Investigations reveal proteinuria (5.5 g/day), hypoproteinaemia and hypercholesterolaemia, urea 10 mmol/L (2.5-7.5) and creatinine 200 mol/L (60-110). Renal biopsy confirms membranous glomerulonephritis.

What will be the most appropriate management to get remission?

- 1- Azathiaprine
- 2- Cyclophosphamide plus methylprednisolone
- 3- Cyclosporin A
- 4- Methylprednisolone
- 5- Protein restriction

Answer & Comments

Answer: 2- Cyclophosphamide plus methylprednisolone

The twin aims of treating membranous nephropathy are

First to induce a remission of the nephrotic syndrome and

Second to prevent the development of end stage renal failure.

A meta-analysis of four randomised controlled studies comparing treatments of membranous nephropathy showed that regimes comprising chlorambucil or cyclophosphamide, either alone or with steroids, were more effective than symptomatic treatment or treatment with steroids alone in inducing remission of the nephrotic syndrome.

A small randomised controlled study of 17 patients with a persistent nephrotic syndrome and declining renal function suggested that ciclosporin A slowed the rate of decline of renal function: this requires confirmation in a larger trial.

[Q: 4376] OnExamination 2012 - Medicine

A 27-year-old patient presented to his GP with persistent cough and weight loss. He had night sweats.

He was diagnosed with TB and referred to the respiratory clinic. He was started on treatment. His urine became orange in colour.

Which one of the following drugs causes this?

- 1- Ciprofloxacin
- 2- Ethambutol
- 3- Isoniazide
- 4- Pyrazinamide
- 5- Rifampicin

Answer & Comments

Answer: 5- Rifampicin

It is very important to be aware of side effects of drugs especially those for TB.

Patients should be warned about this. It can also be used to confirm compliance.

Orange staining occurs to contact lenses.

[Q: 4377] OnExamination 2012 - Medicine

A 32-year-old woman presented with daytime sleepiness and fatigue.

She does not take any regular medications. She denies snoring at night. On detailed history, she describes having episodes of probable cataplexy.

Clinical examination is unremarkable. Thyroid function tests are normal.

The patient is suspected of having narcolepsy.

Which of the following tests will be most useful in diagnosis?

- 1- Genetic analysis
- 2- High hypocretin levels in cerebrospinal fluid (CSF) analysis
- 3- Multiple sleep latency test
- 4- Polysomnography
- 5- Trial of continuous positive airway pressure (CPAP)

Answer & Comments

Answer: 3- Multiple sleep latency test

Cataplexy is an important feature of narcolepsy. There is lower than normal hypocretin levels in CSF. There is high rate of HLA-DBQ1*0602 but this is not diagnostic.

Polysomnography can sometimes be done to exclude obstructive sleep apnoea (OSA) but will not diagnose narcolepsy.

Nasal CPAP is used in treatment of OSA and not used for narcolepsy.

[Q: 4378] OnExamination 2012 - Medicine

A 79-year-old man presents with an ischaemic

stroke and a left hemiparesis.

According to the WHO International Classification of Functioning, Disability and Health, what would be the classification of the left hemiparesis with which he presents?

- 1- Activity limitation
- 2- Impairment of body function
- 3- Participation restriction
- 4- Pathology
- 5- Right total anterior circulation infarct

Answer & Comments

Answer: 2- Impairment of body function

The NICE guidelines on stroke suggest that we use terminology to describe the type of impairment in accordance with the WHO International Classification of Functioning, Disability and Health. Symptoms and signs are classified as 'impairment of body function'.

Answer A is incorrect because the type of impairment classified as 'activity limitation' are difficulties that a patient may have in executing certain activities, for example communication impairment in patients with aphasia following a stroke or the inability to pick up a cup in the affected hand.

Answer C is incorrect because the type of impairment classified as 'participation restriction' are problems a patient may have in social roles - for example as a spouse or parent.

Answer D is incorrect because the type of impairment classified as 'pathology' would be the diagnosis/disease.

Answer E is incorrect as the answer relates to the Oxford Bamford classification for stroke.

[Q: 4379] OnExamination 2012 - Medicine

An 84-year-old lady is admitted to a rehabilitation unit following a stroke.

On admission a Barthel index is performed.

Which of the following best describes the limitations of using the Barthel index in rehabilitation?

- 1- Floor and ceiling effects
- 2- It correlates poorly with other prognostic scales
- 3- It has poor concurrent and predictive validity
- 4- It is not very sensitive
- 5- It is laborious and takes a long time to perform

Answer & Comments

Answer: 1- Floor and ceiling effects

The most widely recognised limitation of the Barthel index is floor and ceiling effects. It basically means that a disabled person can score a maximum score of 100 and still not be independent.

It is poor at differentiating disability in patients who function at a higher level. It also has floor effects as it may incorrectly score patients low who are initially bed bound following a stroke.

Answer B is incorrect because it correlates well with other prognostic scales.

Answer C is incorrect because it has very good concurrent and predictive validity.

Answer D is incorrect because it is very sensitive.

Answer E is incorrect because it only takes 10 minutes to perform.

[Q: 4380] OnExamination 2012 - Medicine

A 72-year-old ex-miner with a significant smoking history and proven diagnosis of COPD is attending chest clinic for review.

He currently takes only a short acting beta agonist (salbutamol). His last FEV₁ was 45%. He feels his symptoms are not currently controlled on his current drug regime.

According to the latest guidelines, what changes should be made to his medication?

- 1- Inhaled corticosteroid (ICS)
- 2- Long acting beta agonist (LABA)
- 3- Long acting beta agonist and inhaled corticosteroid
- 4- Long acting beta agonist and inhaled corticosteroid and long acting muscarinic antagonist
- 5- Long acting muscarinic antagonist (LAMA) and long acting beta agonist

Answer & Comments

Answer: 3- Long acting beta agonist and inhaled corticosteroid

NICE have recently published guidelines for the management of chronic obstructive pulmonary disease (COPD).

Initially a short acting beta agonist or a short acting muscarinic antagonist (LAMA) is advised. However if the patient is persistently breathless or has exacerbation, then additional therapy should be offered.

This will depend on the FEV₁. If greater than 50%, NICE recommends the addition of either a long-acting beta-agonist (LABA) or LAMA. If FEV₁ is less than 50%, NICE recommends either a LABA plus an inhaled corticosteroid (ICS) (in a combination device) or a LAMA.

If exacerbations continue despite this management, then a combination of all three (LABA, ICS and LAMA) should be trialled.

[Q: 4381] OnExamination 2012 - Medicine

A 17-year-old presents to the emergency department with facial and periorbital

oedema. This is the third episode over the past two years, and on each of the previous two occasions the problem has been treated with oral corticosteroids.

On examination he has periorbital and bilateral lower limb pitting oedema. His BP is 125/72 mmHg, pulse is 72 and regular. He has no significant findings on auscultation of the chest.

Investigations show:

Haemoglobin 12.5 g/dl(13.5-17.7)

White cell count $5.0 \times 10^9/L$ (4-11)

Platelets $260 \times 10^9/L$ (150-400)

Serum Sodium 138 mmol/l (135-146)

Serum Potassium 4.2 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

Albumin 24 g/l (35-50)

Urine Protein +++

Which of the following is the most appropriate initial way to treat him?

- 1- Admit for methylprednisolone and cyclophosphamide
- 2- Observe
- 3- Prednisolone 10 mg/day for six weeks
- 4- Prednisolone 60 mg/day for six weeks
- 5- Trial of ramipril

Answer & Comments

Answer: 4- Prednisolone 60 mg/day for six weeks

The repeated cycles of corticosteroid responsive nephrotic syndrome suggest that this individual has minimal change disease. Therefore he is likely once again to respond to high dose prednisolone, with a tapering dose after the first six weeks of therapy.

In patients who fail to respond initially to corticosteroids, cyclophosphamide and chlorambucil are optional second line agents.

[Q: 4382] OnExamination 2012 - Medicine

Which of the following are characteristic electrocardiogram (ECG) features of hypokalaemia?

- 1- Flattened p waves
- 2- ST elevation
- 3- U waves
- 4- Ventricular tachycardia
- 5- Wide QRS

Answer & Comments

Answer: 3- U waves

U waves are characteristic features of hypokalaemia.

Further ECG features of hypokalaemia include ST depression, low amplitude T waves and ventricular fibrillation.

Ventricular tachycardia is thought to be exceedingly rare in hypokalaemia.

The remaining answers are ECG findings typical of hyperkalaemia, together with absent P waves, tall tented t waves, asystole and ventricular fibrillation.

[Q: 4383] OnExamination 2012 - Medicine

On a CT scan of the thorax, which structure is found posteriorly (behind) to the left main bronchus?

- 1- Ascending aorta
- 2- Descending aorta
- 3- Left pulmonary artery
- 4- Right main bronchus
- 5- Superior vena cava

Answer & Comments

Answer: 2- Descending aorta

The following will be seen:

The descending aorta lies behind (posterior to) the left main bronchus.

The ascending aorta is anterior to the pulmonary trunk.

The left pulmonary artery is anterior to the left main bronchus.

The right main bronchus should be beside the left following bifurcation of the trachea.

The superior vena cava can be found next to the ascending aorta.

The oesophagus is also a posterior structure to the left main bronchus.

[Q: 4384] OnExamination 2012 - Medicine

A 42-year-old woman presents to the clinic with a chronic cough.

Which of the following features would increase the suspicion that she is suffering from asthma?

- 1- Associated dizziness
- 2- Chronic cough without wheeze
- 3- Symptoms in response to exercise
- 4- Symptoms corresponding with a cold
- 5- Voice disturbance

Answer & Comments

Answer: 3- Symptoms in response to exercise

The answer is option C, symptoms in response to exercise.

Guidelines from BTS/SIGN on the diagnosis of asthma suggest that the presence of wheeze, breathlessness, chest tightness or cough, particularly if symptoms are worse at night or in the early morning, after exercise, allergy exposure or cold air, are suggestive of the diagnosis.

A family history of atopy or asthma, personal history of atopy, widespread wheeze, low FEV₁ or PEFR also support the diagnosis.

Dizziness, light headedness, voice disturbance and chronic cough without wheeze do not support a diagnosis of asthma.

[Q: 4385] OnExamination 2012 - Medicine

A 36-year-old single woman with a history of asthma comes to the clinic complaining of symptoms of indigestion.

She uses a steroid inhaler and on examination of her oropharynx you can see obvious evidence of candidiasis. You send her for an endoscopy, which unfortunately reveals extensive oesophageal candidiasis.

Which of the following tests would be most important to consider in this patient?

- 1- CD4 count
- 2- Complement testing
- 3- Fasting blood glucose
- 4- HIV antibody testing
- 5- Immunoglobulin testing

Answer & Comments

Answer: 4- HIV antibody testing

The answer is D, HIV antibody testing.

Whilst candidiasis affecting the oropharynx may be a result of poor inhaler technique and deposition of steroid powder within the mouth, it does not usually result in oesophageal candidiasis. The other possible cause of recurrent oral and genital candida infection is diabetes mellitus, although again this would not normally lead to oesophageal disease.

In the case of this patient, immunocompromise should be suspected and HIV considered, with appropriate pre-test counselling.

[Q: 4386] OnExamination 2012 -
Medicine

A 20-year-old student comes to the clinic complaining of dysuria and minor scrotal swelling and pain. He has also noticed a purulent urethral discharge.

On examination his temperature is 37.5 C, his scrotum is mildly swollen and tender and you can express a mucopurulent discharge from his urethral meatus.

Investigations show:

Haemoglobin 13.9 g/dl(13.5-17.7)

White cell count $8.8 \times 10^9/L$ (4-11)

Platelets $269 \times 10^9/L$ (150-400)

Serum Sodium 141 mmol/l (135-146)

Serum Potassium 4.5 mmol/l (3.5-5)

Creatinine 85 micromol/l (79-118)

Urinary chlamydial antigen positive

Which of the following is the most appropriate anti-microbial therapy for him?

- 1- Azithromycin 1 g as single dose
- 2- Ciprofloxacin 500 mg BD for 7 days
- 3- Minocycline 100 mg daily for 9 days
- 4- Norfloxacin 400 mg daily for 7 days
- 5- Penicillin V 500 mg BD for 7 days

Answer & Comments

Answer: 1- Azithromycin 1 g as single dose

The answer is A, azithromycin 1 g as a single dose.

In a student population where compliance may well be a problem, giving a single dose of antibiotics for the treatment of Chlamydia is the most sensible option.

Other options for treatment of Chlamydia include minocycline, although doxycycline causes less gastrointestinal disturbance. Ofloxacin 200 mg BD for seven days is also

considered a potential option according to SIGN guidelines.

He should also be referred to the GUM clinic for screening for other sexually transmitted infections.

[Q: 4387] OnExamination 2012 -
Medicine

A 44-year-old man is brought to the hospital by his boyfriend.

Over the past few weeks he has complained of increasing headaches and nocturnal fevers. His boyfriend is now concerned that over the weekend he has taken to his bed and has become drowsy and confused.

On examination his temperature is 37.80C and BP 150/90 mmHg. He has papilloedema and neck stiffness. He refuses to comply with most of the elements of neurological testing.

Investigations show:

Haemoglobin 11.9 g/dl(13.5-17.7)

White cell count $9.7 \times 10^9/L$ (4-11)

Platelets $204 \times 10^9/L$ (150-400)

Serum Sodium 136 mmol/l (135-146)

Serum Potassium 4.0 mmol/l (3.5-5)

Creatinine 111 micromol/l (79-118)

Glucose 6.7 mmol/l (non fasting)

CSF opening pressure 22cm water turbid appearance

Glucose 6.5 mmol/l/india ink test positive

CT scan Small ventricles but otherwise unremarkable

Which of the following is the most likely diagnosis?

- 1- Cryptococcal meningitis
- 2- HIV dementia
- 3- HIV encephalopathy
- 4- Meningococcal meningitis
- 5- Tuberculous meningitis

Answer & Comments

Answer: 1- Cryptococcal meningitis

The answer is A, cryptococcal meningitis on a background of HIV infection.

The insidious onset seen here, coupled with signs of raised intracranial pressure, normal glucose on CSF sampling and positive india ink test are all strong pointers to the diagnosis of cryptococcal meningitis. India ink smears however are less sensitive and specific than CSF cryptococcal antigen test, which has a sensitivity of greater than 95%, but false negative tests can occur with a low organism burden.

MRI scanning is more sensitive than CT and may show low intensity lesions in the basal ganglia which enhance with gadolinium.

Treatment in this case would be with amphotericin B combined with flucytosine, although good results have also been seen with flucytosine and fluconazole combination therapy.

Despite aggressive intervention however, mortality is still high at around 6%.

[Q: 4388] OnExamination 2012 - Medicine

A 62-year-old man attends a clinic complaining of progressive peripheral oedema, which has got to the stage where by the end of the day he is hardly able to wear his shoes. He has a past history of hypertension which is managed with amlodipine, but nil else of note.

On examination his BP is 155/85 mmHg. His pulse is 78 and regular. His heart sounds are normal and his chest is clear. He has gross pitting oedema to mid shin on both lower limbs.

Haemoglobin 13.9 g/dl(13.5-17.7)

White cell count $7.6 \times 10^9/L$ (4-11)

Platelets $290 \times 10^9/L$ (150-400)

Serum sodium 140 mmol/l (135-146)

Serum potassium 4.0 mmol/l (3.5-5)

Creatinine 135 $\mu\text{mol/l}$ (79-118)

Albumin 24 g/l (35-50)

Urinary protein 3.5 g/24 hr

Renal biopsy: Thickened renal capillary walls seen on biopsy, but with patent lumina.

Which of the following treatments is most likely to affect this patient's prognosis?

1- Cyclophosphamide

2- Prednisolone

3- Ramipril

4- Rituximab

5- Simvastatin

Answer & Comments

Answer: 3- Ramipril

Corticosteroids alone are ineffective in the treatment of membranous nephropathy. A study of alternating monthly treatment with chlorambucil and steroids did suggest some benefit but this is open to debate and has been disputed in a number of review articles.

Rituximab, a B-cell depleting anti-CD20 chimeric monoclonal antibody has shown some benefit in a small proof of concept study, although it is unlikely to be appropriate for widespread use.

In contrast, ramipril is proven to affect both proteinuria and hypertension in patients with a diagnosis of membranous nephropathy, and is therefore the backbone of therapy for this condition.

[Q: 4389] OnExamination 2012 - Misc

A 72-year-old man comes to the surgery with his wife.

She has witnessed two seizures at home, both of which have lasted for no longer than two minutes or so, accompanied by generalised limb jerking and incontinence of urine. He has been very embarrassed about the problem and did not want to come for review. She did not call an ambulance at the time as he seemed to be comfortable afterwards and she did not want the staff to see him "in a mess".

He has a history of cerebrovascular disease having suffered a minor stroke one year earlier, and suffered a myocardial infarction some three years ago. Medication includes ramipril, amlodipine, atorvastatin and aspirin.

On examination in the surgery he looks well. His BP is 142/79 mmHg, his pulse 75 and regular. Neurological examination is unremarkable apart from some very minor loss of co-ordination affecting his left hand. He wants you to arrange some investigations before bothering the hospital doctors.

Investigations show

Haemoglobin 12.1 g/dl(13.5-18)

White cell count $8.2 \times 10^9/L$ (4-10)

Platelets $301 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (134-143)

Potassium 5.1 mmol/l (3.5-5)

Creatinine 149 $\mu\text{mol/l}$ (60-120)

ESR 12(<20)

ECG Sinus rhythm

Inferior Q waves

Which one of the following initial steps would be most appropriate in this case?

- 1- Carotid ultrasound scanning
- 2- EEG
- 3- Start low dose carbamazepine

4- Start low dose sodium valproate

5- Tilt table test

Answer & Comments

Answer: 1- Carotid ultrasound scanning

EEG measurement is less useful in an elderly population, most likely because of structural changes related to age and pre-existing cerebrovascular disease. MRI however may be useful in detecting any structural abnormality such as a tumour, local vascular abnormality or old cerebral infarct.

In patients with a history of previous stroke foci of epileptic activity can occur in the penumbra around the previous infarct. In view of his previous stroke, carotid ultrasound scanning is also an important part of the initial assessment.

Finally, bearing in mind his previous infarct, he should be considered for 72 hour ECG monitoring, to exclude the possibility of a significant cardiac arrhythmia.

[Q: 4390] OnExamination 2012 - Misc

A 68-year-old female attends the falls clinic.

She had multiple falls over the last six months and she has noticed that she has become much more unsteady on her feet. Her husband tells you that she has become very restless at night and that he hardly gets any sleep.

Examination reveals bradykinesia and a jerky rest tremor. Her gait is broad based. She scores 28/30 on a mini mental state examination (MMSE).

Which of the following is the most likely diagnosis?

- 1- Corticobasal degeneration (CBD)
- 2- Idiopathic Parkinson's disease
- 3- Multiple system atrophy (MSA)

4- Progressive supranuclear palsy (PSP)

5- Vascular parkinsonism

Answer & Comments

Answer: 3- Multiple system atrophy (MSA)

Multiple system atrophy (MSA) is a progressive neurodegenerative disease. The above patient fulfils the criteria for a parkinsonian syndrome (and probably has rapid eye movement sleep disorder), but there are a number of red flags alluding to a Parkinson's plus syndrome:

The patient has multiple falls early in the disease

She has cerebellar signs - broad based (ataxic) gait

She has a 'jerky' tremor.

Option A is incorrect. Corticobasal degeneration presents with parkinsonism, but also cognitive impairment (MMSE here is normal). CBD presents with apraxia and this is responsible for the gait disturbance - it does not present with cerebellar signs as it affects the cerebral cortex and basal ganglia.

Option B is incorrect because idiopathic Parkinson's disease does not present with early falls or early postural instability. This feature usually presents late in the course of the disease. It also does not present with cerebellar signs.

Option D is incorrect because PSP does present with early falls (usually backwards) but does not present with cerebellar signs.

Option E is incorrect because the gait in vascular parkinsonism is usually shuffly with short step length and not ataxic. Rest tremor is absent in vascular parkinsonism, but postural tremor may occur.

[Q: 4391] OnExamination 2012 - Misc

An 80-year-old female presents with recurrent falls. She has fallen a few times whilst walking to the toilet at night to pass urine. She always feels light-headed prior to falling and denies palpitations.

She suffers from ischaemic heart disease, hypertension, diabetes mellitus, hypercholesterolaemia, osteoporosis and hypothyroidism. She is taking gliclazide, metformin, ramipril, doxazosin, levothyroxine, aspirin, simvastatin and weekly alendronate.

Her blood pressure is 130/70 mmHg and her pulse is 70 beats per minute and is irregular. She undergoes a medication review as part of a multi-factorial risk assessment.

Which one of the following medications is most likely to be the culprit for her symptoms?

- 1- Alendronate
- 2- Doxazosin
- 3- Levothyroxine
- 4- Metformin
- 5- Ramipril

Answer & Comments

Answer: 2- Doxazosin

The patient has symptoms of postural hypotension and subsequent presyncope.

It may be possible that she has a degree of autonomic dysfunction secondary to diabetes mellitus that would put her at even greater risk of postural hypotension with an alpha blocker. The most likely cause is the alpha blocker doxazosin that is used for hypertension.

Answers A, C, D and E are incorrect because B, doxazosin, is most likely to cause postural hypotension.

[Q: 4392] OnExamination 2012 - Misc

A 65-year-old man with end-stage idiopathic Parkinson's disease dies. His family donates his brain for research purposes.

Which characteristic histopathological structures are you most likely to find?

- 1- Amyloid plaques
- 2- Cerebral arterial atherosclerosis
- 3- Cytoplasmic inclusion bodies
- 4- Lewy bodies
- 5- Neuronal inclusion bodies

Answer & Comments

Answer: 4- Lewy bodies

Lewy bodies are characteristic in

Parkinson's disease

Corticobasal degeneration

Progressive supranuclear palsy

Motor neuron disease and

Ataxia telangiectasia.

Answer A is incorrect because amyloid plaques are characteristic in Alzheimer's dementia.

Answer B is incorrect because cerebral arterial atherosclerosis usually leads to small vessel disease and multi-infarct dementia.

Answer C is incorrect because cytoplasmic inclusion bodies are characteristically found in multi-system atrophy (MSA).

Answer E is incorrect because neuronal inclusion bodies are found in Pick's disease and fronto-temporal dementia.

[Q: 4393] OnExamination 2012 - Misc

An 80-year-old man was seen at the emergency department following a minor fall

and inability to weight bear.

His right leg was shortened and externally rotated. x Ray of the pelvis confirmed fracture neck of femur. However, the orthopaedic surgeon was concerned about the x ray appearance of the pelvis.

Further enquiry revealed that he was becoming increasingly frail and prone to develop respiratory tract infections. He also complains of pain in the lower back worse at night.

Apart from cachexia and pallor his physical examination was normal.

What is the likely diagnosis?

- 1- Chronic osteomyelitis
- 2- Metastatic carcinoma
- 3- Multiple myeloma
- 4- Osteoporosis
- 5- Paget's disease

Answer & Comments

Answer: 3- Multiple myeloma

Metastatic carcinoma is a possibility, but the patient would be expected to have symptoms of the primary malignancy, for example, prostate, lungs.

Osteoporosis and Paget's disease both can present with pathological fractures, but generalised cachexia and recurrent chest infections are against them.

Chronic osteomyelitis is more likely to present with pain in the joint, pyrexia or loss of the joint.

[Q: 4394] OnExamination 2012 - Misc

A 72-year-old lady presents to her GP with fatigue.

Her husband has noticed change in her character and her hair becoming thinner. She also complains of constipation.

Her only medical history is type II diabetes mellitus which is diet controlled.

On examination she has a pale complexion and her skin is dry. Her pulse is 50 beats per minute, regular. The rest of the examination is unremarkable.

The GP considers anaemia and requests a full blood count which shows:

Haemoglobin 9.1 g/dl (115-165)

White cell count $7.2 \times 10^9/L$ (4-11)

Platelets $147 \times 10^9/L$ (150-400)

Mean cell volume 105 fl (80-96)

What is your diagnosis?

- 1- Chronic fatigue syndrome
- 2- Depression
- 3- Diabetes mellitus
- 4- GI malignancy
- 5- Hypothyroidism

Answer & Comments

Answer: 5- Hypothyroidism

The presence of tender points is important to diagnose chronic fatigue syndrome.

Depression is a common cause of lethargy in the elderly; however other causes should be excluded.

Uncontrolled diabetes can cause lethargy and anaemia. However, other features in this scenario cannot be explained.

Occult malignancy is another cause of anaemia. However, weight loss and gastrointestinal (GI) bleeding are important features and change in character is rarely a feature.

[Q: 4395] OnExamination 2012 - Misc

A 75-year-old female presented to the Emergency department with a transient

ischaemic attack.

Her only past medical history is type II diabetes of 20 year duration. Her blood pressure was 140/90 mmHg and ECG showed atrial fibrillation.

Which one of the following is most likely to prevent her from having a stroke?

- 1- ACE inhibitors
- 2- Aspirin
- 3- β blockers
- 4- Insulin
- 5- Warfarin

Answer & Comments

Answer: 5- Warfarin

If warfarin is contraindicated, aspirin should be used.

Reducing blood pressure (BP) by any class of anti-hypertensive reduces the risk of stroke.

HOPE study showed ACE-Is reduce the relative risk of stroke which may be independent of lowering BP.

Tight glycaemic control also reduces the risk of cerebrovascular events, however in the given scenario the strongest stroke prevention strategy is warfarin.

[Q: 4396] OnExamination 2012 - Misc

A 76-year-old lady presented at the rheumatology clinic with pains of six weeks duration in the limbs and back.

She was recently treated by the GP for Bell's palsy without any significant recovery. Apart from right facial nerve palsy, physical examination was unremarkable.

The GP had enclosed the following results:

Hb 12.3 g/dl (11.5-16)

WBC $5.4 \times 10^9/L$ ($4-11 \times 10^9$)

Platelets $178 \times 10^9/L$ ($150-400 \times 10^9$)

Na 143 mmol/l (135-146)

K 3.8 mmol/l (3.5-5.0)

Urea 7.2 mmol/l (10-20)

Creatinine 112 $\mu\text{mol/l}$ (79-118)

Glucose 6.2 mmol/l (3.3 - 4.4)

CPK 97 U/l (24-170)

Bilirubin 18 $\mu\text{mol/l}$ (1 – 22)

AST 22 U/l (1-31)

ALT 25 U/l (5-35)

ALP 830 U/l (45-105)

Albumin 36 g/l (37-49)

Calcium 2.20 mmol/l (2.2-2.6)

Phosphate 1.0 mmol/l (0.8-1.4)

Select the correct diagnosis from the given list.

- 1- Bony metastases
- 2- Cholestasis
- 3- Osteomalacia
- 4- Paget's disease
- 5- Rickets

Answer & Comments

Answer: 4- Paget's disease

Bony metastases produce local bone pain while in this patient the symptoms are rather generalised.

Cholestasis is the wrong answer as it is usually accompanied by some elevation in liver enzymes and bilirubin.

Although in osteomalacia alkaline phosphatase is raised, plasma calcium and phosphate are low.

Rickets is the form of osteomalacia that develops in childhood before epiphyseal closure.

[Q: 4397] OnExamination 2012 - Misc

A 72-year-old man with longstanding Parkinson's comes to the surgery.

He is maintained on high dose L-dopa therapy but is suffering significant on/off phenomena. This is really affecting his life and he feels unable to leave the house and go on excursions with his wife.

Other past history of note includes prostatism for which he takes an alpha-blocker and a 5-alpha reductase inhibitor. He has also suffered a myocardial infarction some five years earlier.

Which one of the following would be the most appropriate next therapeutic option for him?

- 1- Amitriptyline
- 2- Cabergoline
- 3- Change to soluble levodopa before meals
- 4- Entacapone
- 5- Selegiline

Answer & Comments

Answer: 2- Cabergoline

On/off phenomena may be considerably improved either by the addition of cabergoline (a dopamine agonist) or a subcutaneous infusion of apomorphine.

Liquid forms of L-dopa may also be helpful as they allow closer titration of dose, and splitting meals into smaller snacks and one larger evening meal also affects the pharmacokinetics (PK) of L-dopa positively.

[Q: 4398] OnExamination 2012 - Misc

Which of the following statements is true regarding neck of femur fracture?

- 1- Extracapsular fractures have a higher incidence of avascular necrosis compared to intracapsular fractures.

- 2- In the young displaced fractures should be reduced and fixed urgently.
- 3- Internal rotation of the affected limb is a common clinical finding.
- 4- Mortality for elderly patients is >80% at one year.
- 5- Non-union is not a complication.

Answer & Comments

Answer: 2- In the young displaced fractures should be reduced and fixed urgently.

- A. Intracapsular femoral fractures are at increased risk of avascular necrosis due to disruption of the capsular blood supply at the time of injury.
- B. In young patients the fracture should be reduced and fixed early to decrease the risks of avascular necrosis and non-union.
- C. Patients more commonly present with a short, externally rotated limb.
- D. Mortality at one year is approximately 25%.
- C. Patients more commonly present with a short, externally rotated limb.

[Q: 4399] OnExamination 2012 - Misc

A 65-year-old man with hypertension and hypercholesterolaemia is admitted with right sided weakness. He has marked receptive dysphasia.

Examination reveals right sided facial weakness as well as right-sided hemiparesis. Sensation on the right side of the body is also impaired.

The presence of which additional finding would suggest a diagnosis of a left total anterior circulation infarct (L TACI) rather than a left partial anterior circulation infarct (L PACI)?

- 1- Bitemporal hemianopia

- 2- Right homonomous hemianopia
- 3- Left sided visual neglect
- 4- Left homonomous hemianopia
- 5- Right sided visual neglect

Answer & Comments

Answer: 2- Right homonomous hemianopia

Answer A is incorrect, because a bitemporal hemianopia is caused by a lesion of the optic chiasm.

Answer B is correct because a TACI comprises of all three of the following:

Higher cortical dysfunction which includes visuospatial disturbance (in this case visuospatial neglect), dysphasia and/or a decreased level of consciousness

Homonomous hemianopia

Motor and sensory deficits in two or more of the contralateral face/arm/leg.

Answer C is incorrect. Left sided visual neglect may be present in this patient (as part of the higher cortical dysfunction), but a homonomous hemianopia must be present to fulfil the criteria for a TACI. It is important to note that a patient may have normal visual fields, but may still have left-sided visual neglect.

Answer D is incorrect because a right TACI would cause a left homonomous hemianopia and not a right homonomous hemianopia.

Answer E is incorrect because left homonomous hemianopia must be present to fulfil the criteria for a TACI.

[Q: 4400] OnExamination 2012 - Misc

Which of the following is caused by temporal lobe lesions?

- 1- Apraxia
- 2- Astereognosis

- 3- Primitive reflexes
- 4- Visuospatial neglect
- 5- Wernicke's (receptive) aphasia

Answer & Comments

Answer: 5- Wernicke's (receptive) aphasia

Lesions of the frontal lobe include difficulties with task sequencing and executive skills.

Other symptoms include:

Expressive aphasia (receptive aphasias are due to a temporal lobe lesion)

Primitive reflexes

Perseveration (repeatedly asking the same question or performing the same task)

Anosmia and

Changes in personality.

Lesions of the parietal lobe include:

Apraxias

Neglect

Astereognosis (unable to recognise an object by feeling it) and

Vvisual field defects (typically homonymous inferior quadrantanopia).

They may also cause alaculia (inability to perform mental arithmetic).

Lesions of the temporal lobe cause:

Visual field defects (typically homonymous superior quadrantanopia)

Wernicke's (receptive) aphasia

Auditory agnosia, and

Memory impairment.

Occipital lobe lesions include:

Cortical blindness (blindness due to damage to the visual cortex and may present as Anton

syndrome where there is blindness but the patient is unaware or denies blindness)

Homonymous hemianopia and

Visual agnosia (seeing but not perceiving objects - it is different to neglect since in agnosia the objects are seen and followed but cannot be named).

[Q: 4401] OnExamination 2012 - Misc

A 32-year-old patient with type 1 diabetes who is on your clinic list is admitted with sudden loss of vision. You decide to examine the events which led up to this as part of a significant event audit.

Which of the following is part of the process of significant event audit?

- 1- Agreement, implementation and monitoring of necessary changes is an essential part of the process
- 2- Events cannot be reported as part of the QAOF
- 3- Events should not be reported to the National Patient Safety Agency, (NPSA)
- 4- Non-clinical staff should be excluded from the review process
- 5- Sudden loss of vision in a diabetic would not normally constitute a critical event

Answer & Comments

Answer: 1- Agreement, implementation and monitoring of necessary changes is an essential part of the process

As in all audits, agreement of an endorsement for change is an essential part of the process. If problems in this case with current review or scheduling of appointments for retinal photography are identified for example, then changes may be required.

Events should be reported to the NPSA and may be included as part of the QAOF (quality

and outcomes framework). Sudden and unexpected loss of vision in a diabetic is of course a critical incident. Whilst patient's vision may deteriorate over time, sudden visual loss, whilst it does occur, would not be considered the norm.

Non-clinical staff and their working procedures may be an underlying cause of a critical incident; as such their inclusion in the process is crucial.

[Q: 4402] OnExamination 2012 - Misc

A 76-year-old female presents with weakness of the left side of her body. She has no dysphasia.

Examination reveals power of 3/5 in the flexor muscles of the left upper arm and 2/5 in the extensor muscles of the left upper arm. Power in her left leg is 3/5 in the extensor muscles of the left leg and 2/5 in the flexor muscles. She has normal visual fields and sensation is intact.

An abbreviated mental test score is 10/10.

Please select the best option below to classify her stroke.

- 1- Left lacunar infarct (LACI)
- 2- Right lacunar infarct (LACI)
- 3- Right partial anterior circulation infarct (PACI)
- 4- Right posterior circulation infarct (POCI)
- 5- Right total anterior circulation infarct (TACI)

Answer & Comments

Answer: 2- Right lacunar infarct (LACI)

Option A is incorrect because a left lacunar infarct will cause right sided motor symptoms.

Answer B is correct as this patient has a pure motor stroke. This is classified as a lacunar

infarct according to the Bamford classification.

Answer C is incorrect because the patient's symptoms and signs are not consistent with a partial anterior circulation infarct.

Option D is incorrect because the patient's symptoms and signs are not consistent with a posterior circulation infarct.

Option E is incorrect because the patient's symptoms and signs are not consistent with a total anterior circulation infarct.

[Q: 4403] OnExamination 2012 - Misc

A 70-year-old lady consulted her GP for being generally unwell.

She also complained of constant severe headache and pain in the scalp while combing her hair. She has also noticed difficulty in standing up from the squatting position. She denied any visual disturbances.

Her general physical examination was unremarkable and the investigations showed a raised ESR and alkaline phosphatase.

What is an important diagnosis to consider?

- 1- Cervical spondylosis
- 2- Cluster headache
- 3- Hypothyroidism
- 4- Migraine
- 5- Temporal arteritis

Answer & Comments

Answer: 5- Temporal arteritis

Cervical spondylosis can cause occipital headache and numbness due to the entrapment of C2 sensory nerve root.

Hypothyroidism does not cause headaches.

Migraine and cluster headaches often accompany visual symptoms and headache is intermittent and fluctuating in intensity.

[Q: 4404] OnExamination 2012 - Misc

A 76-year-old man was admitted to the medical assessment unit with bleeding per rectum.

He was pain free and haemodynamically stable.

His past medical history included myocardial infarction two years ago, atrial fibrillation and chronic obstructive pulmonary disease.

His medication included digoxin 125 µgrams per day, furosemide 40 mg per day, warfarin 3 mg per day and salbutamol inhaler.

His haemoglobin was 9.6 g/dl on admission. However, ten hours later he suddenly became hypotensive and was resuscitated with two units of Gelofusine and two units of blood.

An emergency GI endoscopy was inconclusive. An angiogram confirmed the diagnosis.

What is the most likely diagnosis?

- 1- Angiodysplasia
- 2- Colonic tumour
- 3- Diverticular disease of the large bowel
- 4- Granulomatous ulceration, that is, Crohn's disease
- 5- Ischaemic colitis

Answer & Comments

Answer: 1- Angiodysplasia

Colonic tumour

Diverticular disease of the large bowel and

Granulomatous ulceration pathology

can be identified at the endoscopy.

Ischaemic colitis can present with massive bleeding, but abdominal pain is a predominant feature.

[Q: 4405] OnExamination 2012 - Misc

An 84-year-old man was referred for investigation of anaemia. He had been feeling weak and lethargic.

His past medical history included diverticular disease and duodenal ulcer.

Investigations showed:

Hb 7.2 g/dl (130-180)

WBC $4.8 \times 10^9/L$ (4-11)

Platelets $182 \times 10^9/L$ (150-400)

MCV 112 fl (80-96)

Iron $32 \mu\text{mol/l}$ (12-30)

TIBC $70 \mu\text{mol/l}$ (45-75)

Serum folate 24nmol/l (2-11)

Serum B₁₂ 270pmol/l (160-760)

TSH 3.4mU/l (0.4-5.0)

LDH 200U/l (10-250)

Blood film: dimorphic picture

Bone marrow aspirate: generalised increase in iron stores

Faecal occult blood: negative.

Which of the following is the correct diagnosis?

- 1- Gastrointestinal blood loss
- 2- Haemolytic anaemia
- 3- Iron deficiency anaemia
- 4- Megaloblastic anaemia
- 5- Sideroblastic anaemia

Answer & Comments

Answer: 5- Sideroblastic anaemia

Sideroblastic anaemia is a condition in which the bone marrow produces atypical nucleated erythroblasts with granules of iron accumulated in the perinuclear membrane (sideroblasts). There is inability of iron utilisation, resulting in disordered haem

synthesis and hence microcytic hypochromic cells and dimorphic blood film.

Sideroblastic anaemia is most often associated with myelodysplastic syndromes, but can also be inherited. In addition, can occur in other bone marrow conditions including myeloma, polycythaemia rubra vera and leukaemia. Secondary causes include rheumatoid arthritis, SLE, chronic infections and hypothyroidism.

Clinical features are those related to anaemia (and or cytopenia). Diagnosis requires bone marrow examination, which shows ring sideroblasts and increased iron stores. Full blood count shows anaemia, with a normal or increased MCV. Serum iron and transferrin saturation are usually high, and the blood film shows a dimorphic population of normal and hypochromic red blood cells. Total iron binding capacity is usually normal.

Treatment is in general supportive, or of the underlying condition. Transfusion can be considered, with care to avoid iron overload.

Megaloblastic anaemia is a broad term, often caused by Vitamin B₁₂ or folate deficiency. Blood film shows macrocytes with hypersegmented polymorphs.

Options A and C are unlikely because of normal serum iron and total iron-binding capacity (TIBC) and negative faecal occult blood.

A normal lactate dehydrogenase (LDH) means haemolytic anaemia is unlikely.

[Q: 4406] OnExamination 2012 - Misc

A 68-year-old man presents for a follow up visit in clinic.

He presented six months ago with short term memory loss, loss of verbal fluency and dysphasia. His wife then reported that he has become 'less tolerant' and 'overreacts'. Examination at that point was normal and he

scored 25/30 on the mini mental state examination.

A CT brain was essentially normal. Full blood count, biochemical tests, thyroid function, B12 and folate were all normal. He scored 19/30 on a repeat MMSE today. He is diagnosed as having probable Alzheimer's disease and is commenced on donepezil.

The drug acts by inhibiting which of the following enzymes?

- 1- Catechol-O-methyl transferase
- 2- Cholinesterase
- 3- Dopamine decarboxylase
- 4- Glutamic acid decarboxylase
- 5- Monoamine oxidase

Answer & Comments

Answer: 2- Cholinesterase

Donepezil is a cholinesterase inhibitor. It increases acetylcholine levels in the brain and has been shown to slow progression of Alzheimer's dementia.

Answer A is incorrect because catechol-O-methyl transferase is responsible for degradation of dopamine, adrenaline and noradrenaline and catechol-O-methyl transferase inhibitors are used in the treatment of Parkinson's disease.

Answer C is incorrect because dopamine decarboxylase degrades dopamine and dopa decarboxylase inhibitors are used in the treatment of Parkinson's disease.

Answer D is incorrect because glutamic acid decarboxylase is responsible for converting glutamic acid into gamma-aminobutyric acid which is an inhibitory neurotransmitter. Inhibition of this enzyme is likely to give rise to uncontrollable movements such as chorea.

Answer E is incorrect because monoamine oxidase breaks down most cerebral neurotransmitters. Monoamine oxidase

inhibitors can be used in the treatment of depression.

www.nice.org.uk/CG42

[Q: 4407] OnExamination 2012 - Misc

A 55-year-old man presents with a right sided rest tremor and slowness of movement.

A year ago he noticed that he could not smell his food. He has not had any falls and his eye movements are normal. His past medical history is unremarkable and he does not take any medication.

Which of the following structures is most likely to be most affected?

- 1- Left cerebellar hemisphere
- 2- Left cerebral neocortex
- 3- Olfactory nerve
- 4- Red nucleus
- 5- Substantia nigra

Answer & Comments

Answer: 5- Substantia nigra

The diagnosis is most likely idiopathic Parkinson's disease.

The patient has a pre-motor symptom of olfactory disturbance and fulfils the UK-PDS brain bank criteria for Parkinson's disease. He is developing motor symptoms due to loss of more than 50% of the dopaminergic neurones in the substantia nigra.

Option A is incorrect because there are no cerebellar signs (he has normal eye movements and no nystagmus).

Option B is incorrect as lesions of the outermost layer of the cerebral cortex present with problems of memory, attention and consciousness.

Option C is incorrect as isolated lesions of the olfactory nerve would not present with tremor.

Option D is incorrect as the red nucleus is responsible for motor coordination of the upper arm and shoulder.

Loss of dopaminergic neurones in the substantia nigra is predominantly responsible for the symptoms in Parkinson's disease.

[Q: 4408] OnExamination 2012 - Misc

An 86-year-old woman presents with a third episode of urinary frequency and dysuria in eight months.

A urine dipstick is positive for leukocytes, but negative for nitrites. Examination of the genito-urinary area reveals marked atrophic vaginitis and she is commenced on topical oestrogen therapy.

Oestrogen exerts its beneficial effect on the urogenital tissue by which of the following?

- 1- Decreasing para-urethral blood flow
- 2- Decreasing urethral closing pressure
- 3- Increasing para-urethral collagen concentration
- 4- Preventing proliferation of Lactobacilli in the vagina
- 5- Increasing vaginal pH

Answer & Comments

Answer: 3- Increasing para-urethral collagen concentration

Option A is incorrect because oestrogen increases para-urethral blood flow.

Option B is incorrect as oestrogen increases urethral closing pressure by increasing para-urethral collagen concentration and organisation.

Option D is incorrect because oestrogen promotes the proliferation of Lactobacilli in the vagina.

Option E is incorrect because oestrogen decreases vaginal pH by preventing Gram negative bacterial colonisation.

[Q: 4409] OnExamination 2012 - Misc

An 82-year-old resident of a residential home was seen at the Emergency department for restlessness and aggressive behaviour.

He has been incontinent of urine and also had few falls. He was placed in the residential home after the death of his wife due to severe arthritis in his hands and knees. His only past medical history includes hypothyroidism, for which he takes thyroxine 50 µgrams per day.

On examination he is disorientated in time, place and person and smells strongly of urine. There are no focal neurological signs.

What is the likely diagnosis?

- 1- Delirium
- 2- Dementia
- 3- Hypoglycaemia
- 4- Myxoedema madness
- 5- Transient ischaemic attack (TIA)

Answer & Comments

Answer: 1- Delirium

Delirium is a common neuropsychiatric syndrome in the elderly characterised by concurrent impairments in cognition and behaviour. There are numerous causes, but it is commonly associated with underlying medical illness and medication. Untreated it has significant morbidity and mortality.

The cardinal features of delirium are recent onset of fluctuating awareness, impairment of memory and attention and disorganised

thinking. Additional features may include visual hallucinations and disturbance of the sleep-wake cycle. Three subtypes are increasingly recognised: hypoactive, hyperactive and mixed.

Delirium is a clinical diagnosis, but there are a number of assessment tools which can aid the clinician. The mini-mental state examination (MMSE) and abbreviated mental test score (AMTS) can assess cognition but not all features of delirium. In the UK (and USA) guidelines recommend the Confusion Assessment Method (CAM) for detecting delirium. The diagnosis requires criteria 1 and 2 to be present, plus either 3 or 4. This has been shown to have a sensitivity and specificity of over 90%:

1. Acute onset and fluctuating course
2. Inattention
3. Disorganised thinking
4. Altered level of consciousness

Distinguishing between delirium and dementia can be difficult, and often they coexist. It is safest to assume delirium is present, and attempt to find an underlying cause before settling on a diagnosis of dementia.

Delirium should be avoided if possible by reducing the risk factors, in particularly predisposing medications. Orientating communication, therapeutic activities, early mobilisation, non-pharmacological approaches to sleep and anxiety, maintaining nutrition and hydration, adaptive equipment for vision and hearing impairment and pain management have also be shown to reduce the incidence.

Immediate identification and treatment of precipitants, withdrawal of culprit drugs and supportive care (correction of hypoxia, hydration, nutrition, mobilisation) are critical in the treatment of delirium. Drug treatment

should be reserved for patients who pose a risk to themselves or others.

A patient on replacement thyroxine is unlikely to have severe hypothyroidism (myxoedema madness) as thyroid-stimulating hormone (TSH) should have been regularly checked. However, non-compliance with medication is possible.

All confused patients should be checked for hypoglycaemia, however, given the information available this is not the answer.

TIA may present with confusion but dysphasia and weakness are prominent symptoms.

[Q: 4410] OnExamination 2012 - Misc

An 80-year-old man was recovering from diarrhoea when he developed difficulty in swallowing and had a choking fit while eating a sandwich.

He took to his bed, complained of back pain, bilateral leg pain, numbness in the feet and could not stand up.

He smoked 20 cigarettes a day and drank 20 units of alcohol each week. Past medical history included bilateral hip replacements and osteoarthritis of both knees.

On examination he was confused with slurred speech. There was bilateral ptosis, ophthalmoplegia and mild proximal weakness in both legs. All tendon reflexes were absent and the plantar responses were equivocal.

He did not co-operate with the examination of the sensory system. The bladder was palpable up to the level of the umbilicus. The prostate was smoothly enlarged and the rectum was full of faeces.

What is the most likely diagnosis?

- 1- Brain stem infarction
- 2- Guillain-Barre syndrome
- 3- Motor neurone disease
- 4- Myasthenia gravis

5- Transverse myelitis

Answer & Comments

Answer: 2- Guillain-Barre syndrome

Guillain-Barre syndrome, also known as acute post infective neuropathy, often follows one to three weeks after an infection. *Campylobacter jejuni* is a well recognised cause of severe GBS.

A brain stem infarct producing bilateral signs is not compatible with life.

Motor neurone disease has a more insidious presentation and does not affect the eye muscles. Myasthenia gravis may present like this.

However, despite muscular weakness, deep tendon reflexes are often preserved and urinary incontinence and diarrhoea may be a feature due to cholinergic crisis.

Transverse myelitis is inflammation of the spinal cord and does not produce brain stem signs.

[Q: 4411] OnExamination 2012 - Misc

A 75-year-old female presented to the Emergency department with a transient ischaemic attack.

Her only past medical history is type II diabetes of 20 year duration.

Her blood pressure was 140/90 mmHg and ECG showed atrial fibrillation.

Which one of the following is the strongest risk factor for stroke?

- 1- Age ? 75
- 2- Atrial fibrillation (AF)
- 3- Diabetes mellitus
- 4- Female sex
- 5- Hypercholesterolaemia

Answer & Comments

Answer: 2- Atrial fibrillation (AF)

The following are risk factors for stroke:

Age (above 65)

Diabetes mellitus and

Hypercholesterolaemia.

Stroke is more common in males than in females. Hence option D is incorrect.

[Q: 4412] OnExamination 2012 - Misc

You are attending a 70-year-old man recently treated for Parkinson's disease, to which treatment he has been showing good response.

His son wants to know how likely he is to develop Parkinson's disease. There is no family history of Parkinson's disease.

What is the correct factor in this case?

- 1- Inheritance pattern of this disease is not known
- 2- It all depends on the exposure to the environmental factors
- 3- Late onset disease is not usually familial
- 4- The disease is autosomal dominant
- 5- The disease is autosomal recessive

Answer & Comments

Answer: 1- Inheritance pattern of this disease is not known

Parkinson's disease is a common neurodegenerative disorder which selectively affects dopaminergic neurons of the substantia nigra, culminating in their destruction. After approximately 50% of the dopamine neurones, and 75-80% of striatal dopamine is lost patients start to exhibit the classical signs of bradykinesia, resting tremor and rigidity.

Despite many years of research, the cause of Parkinson's disease is not fully understood. The relative contribution of genetic and environmental factors still remains unclear. Early studies showed that protoxin n-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) causes parkinsonism in animals and humans. Other environmental toxins have also been linked, but there is no clear causation between exposure and disease.

Up until 10 years ago, it was widely thought that Parkinson's disease was not a genetic disorder. However, since then inherited forms have been identified and there have been a number of genetic findings culminating in the cloning of several genes from loci which have been given the nomenclature PARK1 to PARK 12. ?-synuclein is thought to be an important molecule in the dopaminergic signalling pathways.

In addition single genes have been linked to heritable forms of Parkinson's disease, including SNCA, Parkin, PINK1, DJ1 and LRRK2. The inheritance pattern differs depending on the gene that is altered: LRRK2 and SNCA mutations are autosomal dominant; PARK2, PARK7 and PINK1 are autosomal recessive.

Despite the identification of these genes, the majority of the cases remain idiopathic and therefore the correct answer is option A.

[Q: 4413] OnExamination 2012 - Misc

A 70-year-old alcoholic presented with pain in the left hip joint.

He had been in good health with his only past medical history being of sudden blindness in the right eye which was treated with high dose steroids.

x Ray of the left hip showed severe degeneration of femoral head with loss of joint space.

What is the most likely cause of the joint deformity?

- 1- Age related osteoarthritis
- 2- Avascular necrosis of the femoral head
- 3- Monoarticular rheumatoid arthritis with eye involvement
- 4- Perthes' disease
- 5- Reiter's syndrome

Answer & Comments

Answer: 2- Avascular necrosis of the femoral head

Age related osteoarthritis is incorrect as osteoarthritis is generally bilateral and x ray changes are osteophytes, subchondral sclerosis and subchondral cyst formation.

Rheumatoid arthritis does not cause blindness and the x ray changes include juxta-articular bony erosions, periarticular osteopenia, periarticular soft tissue swelling and joint subluxation.

Perthes' disease is a disease of childhood.

Reiter's syndrome presents more acutely with painful eyes and painful joints. In chronic cases x ray changes are similar to those of RA.

[Q: 4414] OnExamination 2012 - Misc

A 34-year-old man with a known history of Crohn's disease was admitted to hospital with abdominal pain and features of perforation.

He underwent laparotomy and a perforation of the terminal ileum was found with free faecal fluid in the abdominal cavity. He was transferred to the intensive care unit (ITU).

Together with traditional antimicrobial and supportive ITU therapy, which of the following therapeutic measures is most likely to improve this patient's outcome?

- 1- High-dose intravenous corticosteroids

- 2- Low-dose intravenous corticosteroids
- 3- Recombinant anti-endotoxin antibody
- 4- Recombinant human antithrombin III
- 5- Recombinant human tissue-factor pathway inhibitor

Answer & Comments

Answer: 2- Low-dose intravenous corticosteroids

The use of corticosteroids in sepsis remains controversial.

Meta-analyses of all the trials of high-dose steroids (for example, methylprednisolone 1 g) have confirmed that there is either no benefit, or even that there is an adverse effect in septic patients. However, more recent randomised controlled trials have suggested that there is a benefit in sepsis when lower physiological doses of steroids are given.

The precise mechanism is not fully understood, although it is well known that septic patients have low levels of endogenous steroids.

The production of recombinant human anticoagulants has gathered pace in recent years and several products have been tested. There have been randomised clinical trials of recombinant human antithrombin III (Kyber Sept trial), activated protein C (PROWESS trial) and tissue-factor pathway inhibitor (OPTIMIST trial). Of these, only recombinant activated protein C has shown any significant survival benefit at 28 days. However, subsequent studies have failed to demonstrate a survival benefit, and have shown an increased bleeding risk. Activated protein C is therefore no longer recommended for the treatment of sepsis.

[Q: 4415] OnExamination 2012 - Misc

Mr YB is a patient who regularly attends the anticoagulant clinic.

He is very concerned as he has been recently started on a new drug by his GP. He asks you whether it would enhance the anticoagulant effect.

Which of the following may increase the anticoagulant effect in patients taking warfarin?

- 1- Clopidogrel
- 2- Carbamazepine
- 3- Griseofulvin
- 4- Phenobarbitone
- 5- St. John's wort

Answer & Comments

Answer: 1- Clopidogrel

Clopidogrel does not appear to have a clinically relevant effect on the pharmacokinetics or pharmacodynamics of warfarin.

However, the concurrent use of clopidogrel with warfarin, increases the bleeding risk.

All other drugs in the options are C-P450 enzyme inducers so would DECREASE the anticoagulant effect

Stockley Drug Interactions 2011

[Q: 4416] OnExamination 2012 - Misc

A patient on your ward is prescribed warfarin as she has recently been diagnosed with atrial fibrillation. Her desired INR is 2.5

On the morning ward round you take the patient's INR which comes back as 5.2 from the laboratory.

There are no signs of bleeding.

What would be your next course of action?

- 1- Decrease the dose of warfarin
- 2- Do nothing, as there are no signs of bleeding
- 3- Increase the dose of warfarin
- 4- Start a heparin infusion
- 5- Stop the warfarin

Answer & Comments

Answer: 5- Stop the warfarin

The main adverse effect of all oral anticoagulants is haemorrhage.

Checking the INR and omitting doses when appropriate is essential; if the anticoagulant is stopped but not reversed, the INR should be measured two to three days later to ensure that it is falling.

The following recommendations are based on the result of the INR and whether there is major or minor bleeding; the recommendations apply to patients taking warfarin:

Major bleeding - stop warfarin; give phytonadione (vitamin K1) 5-10 mg by slow intravenous injection; give dried prothrombin complex (factors II, VII, IX, and X) 30-50 units/kg (if dried prothrombin complex unavailable, fresh frozen plasma 15 mL/kg can be given but is less effective).

INR 8.0, no bleeding or minor bleeding - stop warfarin and give phytonadione (vitamin K1) 2.5-5 mg by mouth using the intravenous preparation orally [unlicensed use], or 0.5-1 mg by slow intravenous injection (if complete reversal required 5-10 mg by slow intravenous injection); repeat dose of phytonadione if INR still too high after 24 hours; restart warfarin when INR less than 5.0.

INR 5.0-8.0, no bleeding - stop warfarin; minor bleeding - stop warfarin and give phytonadione (vitamin K1) 1-2.5 mg by mouth using the intravenous preparation

orally [unlicensed use]; restart warfarin when INR less than 5.0.

Unexpected bleeding at therapeutic levels - always investigate possibility of underlying cause, for example, unsuspected renal or gastrointestinal tract pathology.

[Q: 4417] OnExamination 2012 - Misc

Mrs HV is taking an antidepressant.

Her husband recently passed away and she was diagnosed as being clinically depressed.

Since taking the antidepressants, she has been complaining of drowsiness, confusion and fatigue.

Depletion of which of the following electrolytes may be causing Mrs HV's symptoms?

- 1- Chloride
- 2- Magnesium
- 3- Phosphate
- 4- Potassium
- 5- Sodium

Answer & Comments

Answer: 5- Sodium

The Committee on Safety of Medicines (CSM) have reported that hyponatraemia is associated with all types of antidepressants; however it has been reported more frequently with selective serotonin reuptake inhibitors (SSRIs) than with other antidepressants.

Hyponatraemia should be considered in all patients who develop drowsiness, confusion or convulsions whilst taking an antidepressant.

BNF 60

[Q: 4418] OnExamination 2012 - Misc

Mr UP is taking bendroflumethiazide for hypertension.

Which of the following is likely to increase whilst on bendroflumethiazide therapy?

- 1- Magnesium
- 2- Potassium
- 3- Sodium
- 4- Uric acid
- 5- White cell count

Answer & Comments

Answer: 4- Uric acid

Hydrochlorothiazide and other thiazide diuretics may cause metabolic disturbances especially at high doses.

They may provoke hyperglycaemia and glycosuria in diabetic and other susceptible patients. They may cause hyperuricaemia and precipitate attacks of gout in some patients.

Thiazide diuretics may be associated with electrolyte imbalances including hypochloraemic alkalosis, hyponatraemia, and hypokalaemia.

Hypokalaemia intensifies the effect of digitalis on cardiac muscle and treatment with digitalis or its glycosides may have to be temporarily suspended. Patients with cirrhosis of the liver are particularly at risk from hypokalaemia.

Hyponatraemia may occur in patients with severe heart failure who are very oedematous, particularly with large doses used with restricted salt in the diet.

The urinary excretion of calcium is reduced. Hypomagnesaemia has also occurred.

Adverse changes in plasma lipids have also been noted but their clinical significance is unclear.

[Q: 4419] OnExamination 2012 - Misc

A patient post retrosternal thyroidectomy resection has sudden onset shortness of breath.

On examination, she is talking clearly but has decreased breath sounds on her right side with hyper-resonance on percussion. Her blood pressure is 110/80 mmHg, pulse 95 beats per minute, respiratory rate 24/min and SpO₂ 92 on air.

Which of the following would be most appropriate for her?

- 1- Chest x ray
- 2- Furosemide 40 mg intravenously
- 3- Intercostal chest drain insertion
- 4- Needle thoracocentesis
- 5- Removal of surgical clips

Answer & Comments

Answer: 1- Chest x ray

According to the scenario above this lady has a pneumothorax.

She is not in extremis (suggesting a tension pneumothorax) so needle thoracocentesis is not required.

The history and examination are suggestive of a pneumothorax and therefore, with her being relatively stable, the most appropriate first step would be confirmation with chest x ray followed by chest drain insertion.

Furosemide would not help.

[Q: 4420] OnExamination 2012 - Misc

A patient needs central venous access for total parenteral nutrition (TPN).

Which of the following is the cleanest site for placement?

- 1- Left femoral

- 2- Left internal jugular
- 3- Right femoral
- 4- Right internal jugular
- 5- Right subclavian

Answer & Comments

Answer: 5- Right subclavian

Right or left subclavian is regarded as the cleanest site for central venous access. It also the most tolerated by patients.

However the incidence of subclinical pneumothorax even in the hands of experienced clinicians has led to it falling out of favour.

[Q: 4421] OnExamination 2012 - Misc

Which of the following statements regarding the internal jugular vein and relations is true?

- 1- Lies medial to the common carotid artery
- 2- On the right side crosses the first part of the subclavian artery
- 3- Originates at the sphenoid sinus
- 4- Passes posterior to the carotid artery
- 5- The right internal jugular is usually smaller than the left

Answer & Comments

Answer: 2- On the right side crosses the first part of the subclavian artery

The anatomy of the jugular vein is important given that it is the site of insertion of central venous catheters.

The internal jugular vein originates at the jugular foramen.

It initially lies posterior and lateral to the carotid artery.

As it descends in the carotid sheath it lies lateral first to the internal then the common carotid artery within the carotid sheath.

It passes anterior to the subclavian artery to join the subclavian vein to form the brachiocephalic vein.

The internal jugular vein receives a lymphatic trunk at its union with the subclavian vein.

The internal jugular vein is usually of considerable size, and the right internal jugular is usually larger than the left.

The external jugular vein drains into the subclavian vein.

[Q: 4422] OnExamination 2012 - Misc

A 64-year-old man is admitted with central epigastric pain. Abdominal x ray shows a dilated bowel loop.

His temperature is 37.0°C, pulse 130 bpm, blood pressure 80/50 mmHg, respiratory rate 29/min, SpO₂ 90% on air.

His full blood count reveals:

Haemoglobin 13.0 g/dl(13.0-18.0)

White cell count $3.2 \times 10^9/L$ (4-11)

Platelets $108 \times 10^9/L$ (150-400)

MCV 105 fl(80-96)

Which of the following is the most appropriate initial treatment of this patient?

- 1- 100% oxygen
- 2- 2 x 14 gauge venflons and 2 litres Hartmann's
- 3- Intensive care
- 4- Intubation and ventilation
- 5- Invasive monitoring

Answer & Comments

Answer: 1- 100% oxygen

This patient has systemic inflammatory response syndrome, possibly caused by acute pancreatitis given the finding of an isolated dilated loop of bowel on abdominal radiograph. However, the initial treatment is the same independent of the underlying cause. All of the above answers are reasonable, however resuscitation of the sick patient still follows the

Airway

Breathing

Circulation

algorithm.

Airway control and oxygen to maintain normal saturations is the first part of that algorithm. Subsequent fluid resuscitation and treatment of the underlying cause can then be initiated. The need for invasive monitoring and intensive care is then assessed, depending on the response to initial treatment.

[Q: 4423] OnExamination 2012 - Misc

A 56-year-old man diagnosed with systemic inflammatory response syndrome (SIRS) secondary to pancreatitis is admitted to the High Dependency Unit. He has a pulse of 109 beats/min and a blood pressure of 89/74 mmHg despite receiving IV fluids and urine output of 25 ml/hour after catheterisation.

Which of the following is the most appropriate course of action for this patient?

- 1- A central line
- 2- A CT abdomen
- 3- A surgical referral
- 4- An arterial line
- 5- Broad spectrum antibiotics

Answer & Comments

Answer: 1- A central line

Early goal directed therapy (EGDT) in cases of SIRS or septic shock is becoming increasingly recognised as potentially beneficial. If fluids are not achieving haemodynamic stability, and there is indication of hypoperfusion as indicated by oliguria or lactataemia, then vigorous resuscitation is indicated.

EGDT aims to increase organ perfusion through restoration of mean arterial pressure using inotropes if necessary, maintaining central venous pressure (CVP), maintaining oxygenation, and using SjVO₂ (jugular venous oxygen saturation) as a guide to oxygen utilisation at the tissue level. SjVO₂ higher than 70% is indicative of organ hypoperfusion, as oxygen is not being extracted.

Insertion of a central line above allows measurement of CVP, SjVO₂ and the use of inotropes.

[Q: 4424] OnExamination 2012 - Misc

Mr TB is prescribed warfarin for prophylaxis of DVT.

Which vitamin does warfarin antagonise?

- 1- A
- 2- B6
- 3- C
- 4- D
- 5- K

Answer & Comments

Answer: 5- K

Warfarin inhibits hepatic vitamin K epoxide reductase, which is an enzyme that converts vitamin K to its active form (hydroquinone).

This results in the impairment of the hepatic synthesis of vitamin K dependent clotting factors (II [prothrombin], VII, IX, and X).

Medical Pharmacology & Therapeutics 3rd Ed, 2010

[Q: 4425] OnExamination 2012 - Misc

Which of the following is not a feature of cannabinoids?

- 1- 9-tetrahydrocannabinol is the active constituent of the resin
- 2- Bioavailability after oral administration is about 70%
- 3- Inhibits eicosanoid synthesis
- 4- Lowers intraocular pressure
- 5- Naloxone blocks the antinociceptive actions of cannabinoids

Answer & Comments

Answer: 2- Bioavailability after oral administration is about 70%

Cannabinoids are derived from the resin of cannabis sativa, and 9-tetrahydrocannabinol (9-THC) is its most important pharmacologically active constituent.

Oral bioavailability of THC whether given in the pure form or as THC in marijuana is low and extremely variable ranging between five and 20% with effects occurring 0.5-3 hours later. Bioavailability of THC in a marijuana cigarette or pipe also rarely exceeds 10 to 20%.

Naloxone and other opioid receptor antagonists block the analgesic actions of cannabinoids.

Synthetic cannabinoids reduce arachidonic acid-induced inflammation by inhibiting eicosanoid production.

[Q: 4426] OnExamination 2012 - Misc

Mr VU is taking amitriptyline for depressive illness.

He comes to see you at a routine outpatient appointment and informs you that he has been experiencing some side effects with his amitriptyline therapy.

Which of the following is classed as a side effect for this drug?

- 1- Gout
- 2- Hypokalaemia
- 3- Renal stones
- 4- Taste disturbances
- 5- Urinary retention

Answer & Comments

Answer: 5- Urinary retention

Many adverse effects of amitriptyline and similar tricyclic antidepressants are caused by their antimuscarinic actions.

Antimuscarinic effects are relatively common and occur before an antidepressant effect is obtained. They include:

Dry mouth

Constipation occasionally leading to paralytic ileus

Urinary retention

Blurred vision and disturbances in accommodation

Increased intraocular pressure and

Hyperthermia.

Tolerance is often achieved if treatment is continued and adverse effects may be less troublesome if treatment is begun with small doses and then increased gradually, although this may delay the clinical response.

Drowsiness may also be common, although a few tricyclic antidepressants possess little or no sedative potential and may produce nervousness and insomnia.

Other neurological adverse effects include:

Headache

Peripheral neuropathy

Tremor

Ataxia

Epileptiform seizures

Tinnitus and

Occasional extrapyramidal symptoms including speech difficulties (dysarthria).

Confusion, hallucinations, or delirium may occur, particularly in the elderly, and mania or hypomania, and behavioural disturbances (particularly in children) have been reported.

Gastrointestinal complaints include:

Sour or metallic taste

Stomatitis and

Gastric irritation with nausea and vomiting.

Orthostatic hypotension and tachycardia can occur in patients without a history of cardiovascular disease, and may be particularly troublesome in the elderly.

Hypersensitivity reactions, such as urticaria and angioedema, and photosensitisation have been reported and, rarely, cholestatic jaundice and blood disorders, including:

Eosinophilia

Bone marrow depression

Thrombocytopenia

Leucopenia and

Agranulocytosis.

Endocrine effects include testicular enlargement, gynaecomastia and breast enlargement, and galactorrhoea. Sexual dysfunction may also occur.

Changes in blood sugar concentrations may also occur, and, very occasionally,

hyponatraemia associated with inappropriate secretion of antidiuretic hormone.

Other adverse effects that have been reported are increased appetite with weight gain (or occasionally anorexia with weight loss). Sweating may be a problem.

Martindale

BNF 60

[Q: 4427] OnExamination 2012 - Misc

You would like to prescribe a selective serotonin reuptake inhibitor (SSRI) for a 14-year-old girl who has been diagnosed as being clinically depressed.

After much debate and intervention from various healthcare professionals, it was decided to prescribe her fluoxetine.

For which one of the following parameters should the patient be closely monitored, especially at the beginning of treatment?

- 1- Coldness of extremities
- 2- Hostility
- 3- Hyperglycaemia
- 4- Prothrombin time
- 5- Tachycardia

Answer & Comments

Answer: 2- Hostility

The balance of risks and benefits for the treatment of depressive illness in individuals under the age of 18 years is considered unfavourable for citalopram, escitalopram, paroxetine and sertraline.

Clinical trials have failed to show efficacy and have shown an increase in harmful outcomes.

Only fluoxetine has shown to be effective in treating depressive illness in children, but careful monitoring for the above sign is required.

BNF 60

[Q: 4428] OnExamination 2012 - Misc

Ms YF is prescribed ciprofloxacin 500 mg twice daily for the treatment of cystitis.

In which of the following conditions should ciprofloxacin be used with caution?

- 1- Asthma
- 2- Diabetes
- 3- Epilepsy
- 4- Glaucoma
- 5- Heart failure

Answer & Comments

Answer: 3- Epilepsy

Quinolones should be used with caution in patients with a history of epilepsy or conditions that predispose to seizures, in glucose-6-phosphate dehydrogenase (G6PD) deficiency, myasthenia gravis (risk of exacerbation), and in children or adolescents.

The CSM has warned that quinolones may induce convulsions in patients with or without a history of convulsions; taking non-steroidal anti-inflammatory drugs (NSAIDs) at the same time may also induce them.

It should also be noted that ciprofloxacin is contraindicated in pregnancy.

BNF 60

[Q: 4429] OnExamination 2012 - Misc

A 10-year-old child presents with a respiratory tract infection. You decide to treat him empirically with a broad spectrum antibiotic.

The child is taking no other medication, has no other co-morbidity factors and has no known detected allergies.

Which of the following antibiotics is contraindicated in this patient?

- 1- Amoxicillin
- 2- Clarithromycin
- 3- Erythromycin
- 4- Flucloxacillin
- 5- Minocycline

Answer & Comments

Answer: 5- Minocycline

Tetracyclines can bind to calcium and deposit on growing bones and teeth. This may cause staining and occasionally dental hypoplasia.

Therefore, tetracyclines should not be given to children under the age of 12 or to pregnant or breastfeeding women.

However, doxycycline can be used (unlicensed) for the treatment of anthrax in children.

[Q: 4430] OnExamination 2012 - Misc

Which of the following statements regarding the internal jugular vein and relations is true?

- 1- Lies lateral to the common carotid artery
- 2- Originates at the carotid canal
- 3- Passes behind the clavicle to join the superior vena cava
- 4- Passes posterior to the subclavian artery
- 5- Receives a lymphatic trunk at its union with the external jugular vein.

Answer & Comments

Answer: 1- Lies lateral to the common carotid artery

The internal jugular vein originates at the jugular foramen.

It initially lies posterior to the carotid artery. As it descends in the carotid sheath it lies

lateral first to the internal then the common carotid artery within the carotid sheath.

It passes anterior to the subclavian artery to join the subclavian vein and then forms the brachiocephalic vein; the left and right brachiocephalic veins unite to form the superior vena cava.

The internal jugular vein receives a lymphatic trunk at its union with the subclavian vein.

The external jugular vein drains into the subclavian vein.

[Q: 4431] OnExamination 2012 - Misc

A 78-year-old male who presents with increasing dysphagia is diagnosed with an inoperable carcinoma of the distal oesophagus. Oesophageal spasm causes food to stick after swallowing which causes odynophagia.

Which drug would be most helpful in relieving his chronic pain?

- 1- Clodronate
- 2- Dexamethasone
- 3- Nifedipine
- 4- Oxybutynin
- 5- Pinaverium

Answer & Comments

Answer: 3- Nifedipine

Nifedipine helps relieve painful oesophageal spasm and tenesmus associated with gastrointestinal tumours and could be used to relieve his odynophagia.

Clodronate inhibits osteoclastic bone resorption and is used to treat malignant bone pain and the associated hypercalcaemia.

Pinaverium is used to reduce the pain duration associated with irritable bowel syndrome (IBS).

Corticosteroids are used to treat pain from central nervous system tumours and painful bladder spasm may be relieved by oxybutynin.

[Q: 4432] OnExamination 2012 - Misc

A 66-year-old male in intensive care who is receiving an escalating noradrenaline infusion (currently at 0.76 mcg/kg/min), has a blood pressure of 90/50 mmHg, pulse of 90 beats per min, a central venous pressure of 10mmHg, capillary refill time of 2-3 seconds has received 2000 mls of colloid in 3 hours. His plasma lactate concentration is 2.9 mmol/l (<1.5).

Which of the following is an appropriate method of measuring adequate intravascular filling?

- 1- LiDCO (lithium dilution cardiac output)
- 2- Oesophageal Doppler monitoring
- 3- PiCCO (pulse contour cardiac output)
- 4- Pulmonary artery flotation catheter (PAFC)
- 5- Transoesophageal echocardiography (TOE)

Answer & Comments

Answer: 3- PiCCO (pulse contour cardiac output)

PiCCO gives indications of cardiac output, extravascular lung water, intravascular filling and only requires a central line and a PiCCO femoral arterial line and as such is relatively simple to use.

It would also not be unreasonable to insert an oesophageal Doppler device; however they have greater interobserver variation and require a degree of experience to use and are prone to misplacement.

LiDCO is still not validated or practical to be widely used.

PAFC are used widely in the USA however a study has questioned their safety and they have fallen out of favour in the UK.

TOE requires considerable expertise to use and is not suitable for cardiac output studies.

[Q: 4433] OnExamination 2012 - Misc

A 56-year-old man with severe brain damage is apnoeic, unsedated, and temperature 36.9°C.

He is intubated and ventilated. His biochemistry is normal.

The combination of which of the following specialists would be able to confirm brain stem death?

- 1- Consultant/specialist trainee with one years experience
- 2- Consultant/specialist trainee with three years experience
- 3- Consultant/specialist trainee with four years experience
- 4- Consultant/specialist trainee with five years experience
- 5- Consultant/specialist trainee with two years experience

Answer & Comments

Answer: 4- Consultant/specialist trainee with five years experience

The conventional criteria previously established for clinical death were based upon lack of cardiorespiratory function.

The development of organ transplantation highlighted patients who had conditions incompatible with life, but who continued to have some form of cardiorespiratory function with artificial support. This led to a code of practice for the diagnosis of brainstem death.

This is based on the knowledge that when the brainstem is damaged to such a degree that its functions are irreversibly destroyed, the heart will inevitably stop beating shortly afterwards. When this occurs, therefore, the patient is dead even though respiration and circulation can be artificially maintained. Brain stem function is checked through set criteria, and the findings must be agreed by at least two senior doctors. One should be a consultant, and the other must have at least five years post registration who has experience in the testing of brain stem death.

'Life-support' should be withdrawn at this point, but consideration should be taken as to whether the person would be a suitable organ donor.

[Q: 4434] OnExamination 2012 - Misc

A 56-year-old man with septic shock is fully ventilated, on continuous veno-venous haemofiltration receiving noradrenaline, vancomycin and ciprofloxacin.

He has a mean arterial pressure [MAP] of 60 mmHg which is then not improved after changing from noradrenaline to adrenaline. There is no evidence of myocardial dysfunction.

Which of the following would be the most appropriate next step in managing this patient?

- 1- ACTH stimulation test
- 2- Activated protein C
- 3- Change of inotropes
- 4- Hydrocortisone
- 5- Nitric oxide

Answer & Comments

Answer: 4- Hydrocortisone

Adrenaline is the first choice for change of inotropes if blood pressure is unresponsive to noradrenaline or dopamine.

The current 'Surviving Sepsis' guidelines do not recommend an adrenocorticotrophic hormone (ACTH) stimulation test prior to administration of hydrocortisone. Hydrocortisone is preferable to dexamethasone. The addition of fludrocortisone to hydrocortisone is optional.

Activated protein C may be prescribed if there is sepsis-related organ dysfunction and a high risk of death (APACHE II 25 or more).

Changing inotropes again would probably not be effective.

Nitric oxide is a non-proven therapy in adult respiratory distress syndrome (ARDS).

This is a complicated area and difficult to remember if you are not regularly on ITU.

[Q: 4435] OnExamination 2012 - Misc

Mr YB is admitted on your ward with endocarditis and is prescribed vancomycin IV.

You monitor the patient for signs of toxicity as it has a narrow therapeutic index.

Which of the following is a result of vancomycin toxicity?

- 1- Bradycardia
- 2- Dry mouth
- 3- Erythema multiforme
- 4- Hepatotoxicity
- 5- Ototoxicity

Answer & Comments

Answer: 5- Ototoxicity

Ototoxicity is associated with vancomycin, and is more likely in patients with high plasma concentrations, or with renal impairment or pre-existing hearing loss.

It may progress after drug withdrawal, and may be irreversible. Hearing loss may be preceded by tinnitus, which must be regarded as a sign to stop treatment.

The important level to measure here is the trough level as opposed to the peak level with gentamicin.

(Martindale)

[Q: 4436] OnExamination 2012 - Misc

A 56-year-old man is admitted with epigastric pain after drinking heavily.

He has a temperature of 36.9°C, a pulse of 95/min, a blood pressure of 85/60 mmHg, and a respiratory rate of 32/min.

Investigations reveal:

Haemoglobin 12.6 g/dl(13.0-18.0)

Platelets $169 \times 10^9/L$ (150-400)

White cell count $3.9 \times 10^9/L$ (4-11)

Which of the following is the diagnosis?

- 1- Leaking aortic aneurysm
- 2- Multi-organ dysfunction syndrome (MODS)
- 3- Severe sepsis
- 4- Septic shock
- 5- Systemic inflammatory response syndrome (SIRS)

Answer & Comments

Answer: 5- Systemic inflammatory response syndrome (SIRS)

This patient has features of pancreatitis. He also has hypotension, and leucopenia. He therefore fulfils the criteria for systemic inflammatory response syndrome. This is equivalent to sepsis, but occurs in the absence of infection (e.g. in pancreatitis).

SIRS is defined as two or more of the following:

Temperature more than 38°C or less than 36°C.

Heart rate more than 90 beats/min.

Respiratory rate more than 20 breaths/min or PaCO₂ less than 4.3kPa.

WBC count $12,000/mm^3$, less than $4000/mm^3$, or more than 10% immature (bands) form.

A leaking aortic aneurysm is still a possibility, however a decreased white cell count would not be expected.

We do not have enough information to diagnose multi-organ dysfunction. There is no evidence of infection to make a diagnosis of septic shock or severe sepsis. For information, sepsis is defined as the association of systemic inflammatory responses with evidence of microbial origin. Severe sepsis also has hypoperfusion or dysfunction of at least one organ system, and septic shock is this plus hypotension refractory to fluid resuscitation.

[Q: 4437] OnExamination 2012 - Misc

An 82-year-old lady was admitted to hospital with fever and confusion.

On examination her temperature was 39°C, blood pressure was 80/45 mmHg with a pulse of 110 beats per minute regular with numerous petechiae over the abdomen.

After taking blood, it was noted that there was continued bleeding from the venous puncture site.

A urinary catheter was inserted and yielded 1500 ml of cloudy yellow offensive-smelling urine.

Which of the following is correct concerning this patient?

- 1- Circulating levels of activated protein C (aPC) will be reduced
- 2- Levels of D dimer will be reduced

- 3- Levels of fibrin degradation products (FDPs) will be reduced
- 4- The activated partial thromboplastin time (APTT) will be below the normal range
- 5- The platelet count is likely to be elevated

Answer & Comments

Answer: 1- Circulating levels of activated protein C (aPC) will be reduced

The patient has disseminated intravascular coagulation (DIC) secondary to sepsis.

Given the history, the most likely source is the urinary tract.

Several coagulation abnormalities are seen in sepsis including:

APTT elevated

PT elevated

FDPs elevated

D dimers elevated

Platelets reduced

Fibrinogen reduced

Protein C reduced

Antithrombin reduced.

[Q: 4438] OnExamination 2012 - Misc

A 67-year-old man complains of dizziness and faintness. He has insulin dependent diabetes mellitus and he had a sigmoid colectomy three days previously.

His blood pressure is 80/50 mmHg, his pulse 110 beats per min, his respiratory rate 24/min, and he has SpO₂ 99% on air. His plasma glucose concentration is 18 mmol/l (3.0-6.0 fasting).

Which of the following is the most appropriate investigation for this patient?

- 1- Arterial blood gas

- 2- Chest x ray
- 3- Electrocardiogram
- 4- Serum lactate
- 5- Urine ketones

Answer & Comments

Answer: 3- Electrocardiogram

This man may have a cardiac cause for his dizziness. The highest prevalence of myocardial infarction (MI) is 72 hours post-operation. Patients with diabetes may not have chest pain due to autonomic dysfunction.

The differential diagnosis would include pulmonary embolus. It may also include diabetic ketoacidosis, but this would be unlikely with his glucose at 18 mmol/L and would not directly explain his hypotension. Also, he would be expected to have a slightly higher respiratory rate than 24/min.

The most appropriate immediate investigation in this scenario would be ECG.

[Q: 4439] OnExamination 2012 - Misc

A 23-year-old man with known peanut allergy presented to the Emergency department with anaphylaxis. He has a swollen face and lips.

His BP is 90/60 mmHg, pulse 110 bpm and he is wheezy.

Which of the following formulations of adrenaline should be given?

- 1- 0.5 ml of 1:10000 adrenaline IM
- 2- 0.5 ml of 1:1000 adrenaline IM
- 3- 5 ml of 1:1000 adrenaline IM
- 4- 10 ml of 1:10000 adrenaline IV
- 5- Nebulised adrenaline

Answer & Comments

Answer: 2- 0.5 ml of 1:1000 adrenaline IM

For adults, a dose of 0.5 mL adrenaline 1:1000 solution (500 micrograms) should be administered intramuscularly, and repeated after about five minutes in the absence of clinical improvement or if deterioration occurs after the initial treatment especially if consciousness becomes - or remains - impaired as a result of hypotension.

The intramuscular (IM) route for adrenaline is the route of choice for most healthcare providers. There is a much greater risk of causing harmful side effects by inappropriate dosage or misdiagnosis of anaphylaxis when using IV adrenaline.

Adult EpiPen which allergy sufferers can carry with them contains 0.3 mg or 0.15 mg adrenaline in a 1:1000 dilution for intramuscular (IM) injection.

[Q: 4440] OnExamination 2012 - Misc

Which of the following statements regarding the subclavian vein and its relations is correct?

- 1- Begins at the lateral border of the first rib
- 2- Forms the axillary vein
- 3- Joins the superior vena cava
- 4- The subclavian vein and internal jugular vein form the brachiocephalic trunk
- 5- The subclavian vein passes posterior to scalenus anterior.

Answer & Comments

Answer: 1- Begins at the lateral border of the first rib

The subclavian vein is a continuation of the axillary vein, beginning at the lateral border of the first rib.

It passes anterior to scalenus anterior.

The subclavian and internal jugular vein unite to form the brachiocephalic vein,

subsequently the left and right brachiocephalic veins unite to form the superior vena cava.

The brachiocephalic trunk is a branch of the aortic arch, which divides to form the right subclavian and right common carotid arteries.

[Q: 4441] OnExamination 2012 - Misc

An 18-year-old male is admitted with a history of diarrhoea and vomiting associated with weakness and lethargy.

His motor power in the distal arms and legs is decreased and he describes difficulty swallowing. His forced vital capacity (FVC) is 1.5 litres.

Which of the following is the most appropriate immediate treatment for this condition?

- 1- Cyclophosphamide
- 2- Intravenous immunoglobulin therapy (IgG) 0.5 g/kg
- 3- Intubation and ventilation
- 4- Plasmapheresis
- 5- Prednisolone 60 mg

Answer & Comments

Answer: 2- Intravenous immunoglobulin therapy (IgG) 0.5 g/kg

This scenario is suggestive of Guillain-Barre syndrome (GBS).

Dysphagia is a dangerous symptom suggestive of bulbar involvement. However a FVC of 1.5 litres is not an indication for immediate ventilation (less than 1 litre is).

First line therapy is intravenous IgG.

Plasmapheresis can also be used but requires specialist equipment.

Steroids are of no benefit.

Cyclophosphamide although an immune suppressant is a red herring.

[Q: 4442] OnExamination 2012 - Misc

A 67-year-old man is three days post-operation for a sigmoid colectomy. He has insulin dependent diabetes mellitus. He complains of dizziness and faintness.

His blood pressure is 80/50 mmHg, his pulse is 110 bpm, he has a respiratory rate 24/min, and he has SpO₂ 99% on air. His blood glucose is 18 mmol/L (3.0-6.0 fasting).

His electrocardiogram shows ST depression of 2 mm in leads II, III and AVF.

Which of the following is the initial drug therapy for this patient?

- 1- Aspirin 300mg
- 2- Clexane 1 mg/kg subcutaneously
- 3- Clopidogrel 75 mg
- 4- Diamorphine 2.5 mg
- 5- Glycerol tri-nitrate 800 mcg sublingually

Answer & Comments

Answer: 1- Aspirin 300mg

Initial treatment of an acute coronary syndrome is aspirin 300 mg. This should be safe in the post-surgical patient with no signs of bleeding at three days post operation. Clexane would also be given, but aspirin initially.

The dose of clopidogrel is 300 mg in an acute coronary syndrome.

Diamorphine is used to treat anxiety and pain, neither of which is commented upon.

GTN would be reasonable to try, however the blood pressure is low.

Remember that in the diabetic chest pain may not be a feature of acute coronary syndrome due to autonomic dysfunction, and

in most post-surgical patients myocardial infarct is silent.

[Q: 4443] OnExamination 2012 - Misc

You are asked to see a 64-year-old man post oversew of a duodenal ulcer.

He is confused. His SpO₂ is 97 on oxygen. Pulse 110 beats per minute, blood pressure 100/50 mmHg, respiratory rate 32/min and his urine output is 10 ml in the last hour.

Which of the following is the most appropriate treatment for this man?

- 1- 100% oxygen via face mask
- 2- Central line and arterial line
- 3- Colloid 500 ml stat
- 4- Haloperidol 2.5 mg intravenously
- 5- Noradrenaline via central line

Answer & Comments

Answer: 3- Colloid 500 ml stat

Post-operative confusion is common in the elderly however this can be caused by a low perfusion state.

His observations are indicative of underfilling/dehydration.

Of the options given a fluid bolus is reasonable. Some would argue that 100% oxygen comes before fluids but with an SpO₂ of 97 it is unlikely that hypoxia is contributing to his problems (nonetheless oxygen therapy would be recommended).

The other options would come further down the line if initial interventions were unsuccessful and he deteriorated.

[Q: 4444] OnExamination 2012 - Misc

A 64-year-old man is admitted with central epigastric pain.

Abdominal x ray shows a central dilated bowel loop. His temperature is 37.0°C, pulse 130 beats per min, blood pressure 80/50 mmHg, respiratory rate 29/min and SpO₂ 90 on air.

His full blood count reveals:

Haemoglobin 13.0 g/dl (13.0-18.0)

White cell count $3.2 \times 10^9/L$ (4-11)

Platelets $108 \times 10^9/L$ (150-400)

MCV 105 fl (80-96)

Which of the following is the most likely diagnosis?

- 1- Gall stone ileus
- 2- Ischaemic bowel
- 3- Pancreatitis
- 4- Perforated duodenal ulcer
- 5- Small bowel obstruction

Answer & Comments

Answer: 3- Pancreatitis

Ischaemic bowel and perforated duodenal ulcer would be high in the differential list. However the history and raised mean corpuscular volume (MCV) suggests alcohol use and the severity of his observations would suggest a systemic inflammatory response which is more common with pancreatitis.

Acute pancreatitis has a mortality of 7-10%, often due to sepsis or multi-organ failure. There are a number of scoring systems which can be used to guide prognosis, but they are unreliable within the first 48 hours of the illness. Gallstones account for 50% of cases, with the majority of the rest being associated with alcohol.

Patients typically present with severe epigastric pain which radiates to the back and vomiting. As seen in this example, there is often a systemic inflammatory response. Amylase is markedly raised, often in excess of

four times the normal value. Early complications include ARDS (adult respiratory distress syndrome), acute kidney injury and disseminated intravascular coagulation (DIC).

Treatment is essentially supportive, and high levels of monitoring are usually required (often in the intensive care unit). Those patients who are found to have gallstones should be considered for emergency ERCP, and all should have a cholecystectomy during the same admission.

[Q: 4445] OnExamination 2012 - Misc

A 22-year-old woman comes to the genetics clinic for advice.

She has a family history of Parkinson's disease. Her brother was recently diagnosed with Parkinson's at the age of 26, her father was previously diagnosed at the age of 56, and her grandfather at the age of 69.

Which of the following phenomena is exhibited here?

- 1- Autosomal dominance
- 2- Complete penetrance
- 3- DNA methylation
- 4- Genetic anticipation
- 5- Incomplete penetrance

Answer & Comments

Answer: 4- Genetic anticipation

Autosomal dominance has no bearing on whether the condition presents at a younger age with successive generations, although familial Parkinson's is usually a dominant disorder.

DNA methylation does change gene expression but is not thought to be the cause of anticipation seen here.

Complete and incomplete penetrance refers to the range of symptoms seen with a particular condition.

[Q: 4446] OnExamination 2012 - Misc

A 16-year-old boy presents with chronic pain in his left thigh over the past few months. He has seen his GP on four occasions and has been given paracetamol and told that these are growing pains.

The pain has now reached the point that he refuses to mobilise beyond walking around the house.

On examination his BP is 132/72 mmHg, pulse is 67 and regular. Clinical examination is unremarkable apart from the fact that he appears tender over the left femur.

Investigations show:

Haemoglobin 12.2 g/dl(13.5-17.7)

White cell count $8.0 \times 10^9/L$ (4-11)

Platelets $178 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.3 mmol/l(3.5-5)

Creatinine 120 $\mu\text{mol/l}$ (79-118)

Alanine aminotransferase 44 U/l (5-40)

Alkaline phosphatase 780 U/l (39-117)

Which of the following is the most likely diagnosis?

- 1- Hepatoma
- 2- Osteosarcoma
- 3- Paget's disease
- 4- Rickets
- 5- Stress fracture

Answer & Comments

Answer: 2- Osteosarcoma

Hepatoma in the presence of normal transaminases is extremely unlikely.

Paget's disease, whilst associated with a raised alkaline phosphatase does not usually occur in this age group.

Rickets would not be expected to occur in a single bone, and a stress fracture would not present with many months of pain.

[Q: 4447] OnExamination 2012 - Misc

A 38-year-old woman presents with pain down the lateral aspect of her right hip. She had completed a half marathon for charity the previous weekend, but had previously only managed around seven to eight miles in training runs.

She says she noticed the pain after she had warmed down after the run, and says that all hip movements and weight bearing seem to make the pain much worse. It also seems to radiate down to the lateral aspect of her thigh, and she has problems lying on the affected side due to pain.

On examination she has point tenderness over the greater trochanter.

Investigations show

Haemoglobin 12.9 g/dl(13.5-18)

White cell count $4.5 \times 10^9/L$ (4-10)

Platelets $201 \times 10^9/L$ (150-400)

ESR 12 mm/hr(1-20)

Hip x ray Normal

Which of the following is the most likely diagnosis?

- 1- Avascular necrosis of the hip
- 2- Osteoarthritis of the hip
- 3- Septic arthritis of the hip
- 4- Tendonitis
- 5- Trochanteric bursitis

Answer & Comments

Answer: 5- Trochanteric bursitis

This patient has a global reduction in movement affecting the right hip, and point tenderness over the trochanter indicates trochanteric bursitis very strongly. Both local trauma and an unaccustomed period of exercise may precipitate symptoms.

Management involves both appropriate physiotherapy and use of non-steroidals.

Some advocates support local corticosteroid injection, and one randomised controlled trial has shown a prolonged benefit with use of hydrocortisone and lidocaine.

[Q: 4448] OnExamination 2012 - Misc

Which of the following is associated with cavitation on the chest X-ray?

- 1- Klebsiella pneumonia
- 2- Legionnaires' disease
- 3- Pneumococcal pneumonia
- 4- Sarcoidosis
- 5- Viral pneumonia

Answer & Comments

Answer: 1- Klebsiella pneumonia

Cavitating lesions are caused by:

- squamous cell carcinoma
- abscess (Staph. aureus, Klebsiella and Pseudomonas aeruginosa)
- lymphoma
- rheumatoid nodule
- pulmonary infarction or
- Wegener's granulomatosis.

[Q: 4449] OnExamination 2012 - Misc

You are asked to see a 78-year-old man who has been admitted to the ward for terminal

care after a massive subarachnoid haemorrhage.

He is unconscious but the nurses are concerned that he has pooling of secretions, tries to cough and becomes distressed.

On examination he is unconscious, but has a respiratory rate of 30 and has a death rattle. He is receiving diamorphine via a syringe driver.

Which of the following is the most appropriate treatment for him?

- 1- Atropine nebulisers
- 2- Hyoscine administered subcutaneously
- 3- Increase the dose of diamorphine via the syringe driver
- 4- Salbutamol nebulisers
- 5- Saline nebulisers

Answer & Comments

Answer: 2- Hyoscine administered subcutaneously

The answer is hyoscine s/c which can be given up to three times per day in boluses of 10-20 mg.

Both hyoscine and atropine when given subcutaneously are thought to be equally appropriate for drying up secretions.

Whilst both atropine and salbutamol given in nebulised form are bronchodilators, they are unlikely to be effective in relieving his symptoms.

Saline nebulisers are only likely to irritate him further and cause worsening coughing.

Increasing his diamorphine may be associated with significant risk of hastening a respiratory arrest.

[Q: 4450] OnExamination 2012 - Misc

A 47-year-old patient with metastatic breast

cancer is admitted for bisphosphonate infusion for severe bone pain.

With help from the palliative care team the GP has tried several medications without significant benefit. The patient agrees to admission for a bisphosphonate infusion. She asks about side effects of bisphosphonates.

Which complication or side effect is more likely to occur when bisphosphonates are used in cancer-related symptoms?

- 1- Diarrhoea
- 2- Hypocalcaemia
- 3- Oesophageal erosions
- 4- Osteonecrosis of the jaw
- 5- Renal failure

Answer & Comments

Answer: 4- Osteonecrosis of the jaw

The risk of osteonecrosis of the jaw is much greater for patients receiving intravenous bisphosphonates in the treatment of cancer.

MHRA/CHM advice is as follows:

'Risk factors for developing osteonecrosis of the jaw that should be considered are: potency of bisphosphonate (highest for zoledronate), route of administration, cumulative dose, duration and type of malignant disease, concomitant treatment, smoking, comorbid conditions, and history of dental disease.

All patients receiving bisphosphonates for cancer should have a dental check-up (and any necessary remedial work should be performed) before bisphosphonate treatment.

However, urgent bisphosphonate treatment should not be delayed, and a dental check-up should be carried out as soon as possible in these patients. All other patients who are prescribed bisphosphonates should have a

dental examination only if they have poor dental health.'

The likelihood of other side effects is not dependent on an underlying cancer diagnosis.

[Q: 4451] OnExamination 2012 - Misc

You are caring for a patient with metastatic uterine cancer who is in pain.

Her GP has been treating her in line with the WHO analgesic ladder. She has been started on codeine as step two on the ladder. Unfortunately she gains no additive analgesic effect from codeine.

What is the likely mechanism for this poor response to codeine?

- 1- Concomitant use of cyclizine
- 2- Concomitant use of prednisolone
- 3- CYP2D6 poor metaboliser
- 4- Hypercalcaemia
- 5- Renal impairment

Answer & Comments

Answer: 3- CYP2D6 poor metaboliser

The analgesic effect of codeine depends on its conversion to morphine by the CYP2D6 hepatic enzyme.

Up to 10% of Caucasians are CYP2D6 poor metabolisers and are unlikely to derive any analgesia from it.

If hepatic metabolism is impaired for any other reason (drugs or hepatic impairment) patients are also unlikely to benefit from codeine.

[Q: 4452] OnExamination 2012 - Misc

A patient with a history of pancreatic cancer complains of central abdominal pain.

The patient is not constipated and his most recent blood tests were unremarkable. His GP has started him on paracetamol 1 g QDS and asks you, as the speciality doctor in palliative medicine, for advice on how to improve his pain relief.

What is the most appropriate drug choice?

- 1- Codeine 8 mg + paracetamol
- 2- Codeine 30 mg + paracetamol
- 3- Double dose of PCM
- 4- Oramorph
- 5- Tramadol

Answer & Comments

Answer: 2- Codeine 30 mg + paracetamol

This question requires knowledge of the WHO analgesic ladder.

This underpins the management of cancer (and non-cancer) pain management. It provides a step-wise management strategy to pain relief.

Step one is simple analgesia

Step two uses a weak opioid plus a non-opioid.

This patient has not gained relief from step one so moving to step two (that is, codeine 30 mg plus paracetamol) is the logical next choice of those available here.

Codeine 8 mg in combination with paracetamol has not been convincingly shown to offer greater analgesic benefit over paracetamol alone and is therefore not recommended (as patients can develop codeine side effects).

[Q: 4453] OnExamination 2012 - Misc

You are working as a palliative medicine speciality doctor and you are asked to assess

and admit a 56-year-old woman with metastatic lung cancer to the local hospice.

She was diagnosed with cancer two months ago and has been increasingly troubled with low back pain. Her GP has been increasing doses of morphine without effect. The GP asked for admission for help with symptom control.

On questioning the patient complains of low back pain with occasional feeling of weakness and 'tingling' in her legs. There has been no bowel or bladder disturbance.

On examination there is some tenderness over L2 and power in both legs is slightly reduced. There are no other abnormalities to find.

What is the most appropriate management?

- 1- Arrange lumbar x ray
- 2- Arrange urgent MRI
- 3- Bed rest
- 4- Increase analgesia and arrange physiotherapy
- 5- Urgent referral to local oncology service

Answer & Comments

Answer: 5- Urgent referral to local oncology service

Metastatic spinal cord compression (MSCC) is defined as spinal cord or cauda equina compression by direct pressure and/or induction of vertebral collapse or instability by metastatic spread or direct extension of malignancy that threatens or causes neurological disability. The true incidence of MSCC in England and Wales is not known but studies have suggested it is as much as 80 cases per million per year (approximately 4000 per year). MSCC is a medical emergency, and a low index of suspicion is required as the initial features may be non-specific. Recent studies have shown the median times from the onset of back pain and nerve root pain to referral were 3 months and 9 weeks

respectively. Nearly half of all patients with MSCC were unable to walk at the time of diagnosis and of these, 67% had recovered no function after 1 month.

In this scenario, there is a significant chance of MSCC and you are in an out-of-hospital setting so urgent referral to the oncologists is the most appropriate answer. NICE guidance recommends this is done immediately in anybody with neurological symptoms and signs, and patients transferred to a unit with 24-hour capability for MRI and definitive treatment of MSCC. The oncologists are likely to recommend high dose dexamethasone whilst awaiting transfer.

If you were in a hospital setting you would want to discuss the case with the oncologists and orthopaedic surgeons and organise an MRI scan. This MRI should be of the whole spine, unless there is a specific contraindication. NICE recommends it be done within 24 hours in patients with neurological signs, and within one week if there is spinal pain suggestive of metastases. Occasionally the MRI should be done sooner if there is a pressing clinical need for emergency surgery, but out of hours MRI should only be performed in clinical circumstances where there is an emergency need and intention to proceed immediately to treatment. This should therefore be decided by either the oncology or orthopaedic team.

Definitive treatment of MSCC is either surgery or radiotherapy. At present, relatively few patients with MSCC in the UK receive surgery. However, research evidence suggests that early surgery may be more effective than radiotherapy at maintaining mobility in a selected subset of patients.

[Q: 4454] OnExamination 2012 - Misc

You are currently working on a respiratory ward and looking after a patient with

mesothelioma. She was diagnosed with mesothelioma six months before and has deteriorated rapidly.

She was admitted with breathlessness and a pleural effusion was diagnosed, but not drained. Thirty six hours after admission the patient passed away. You are called by the bereavement office to complete the death certificate as soon as possible as the family wishes to arrange the funeral for early the following week.

Which is the most appropriate action to take?

- 1- Ask consultant to complete the death certificate
- 2- Complete the death certificate yourself as you know the family
- 3- Discuss the case with the patients oncologist
- 4- Discuss with the patients GP to confirm the diagnosis
- 5- Refer to the coroner's office.

Answer & Comments

Answer: 5- Refer to the coroner's office.

Patients with mesothelioma must be referred to the coroner's office as it is considered an industrial disease.

The coroner will often request a limited post mortem to confirm the diagnosis and an inquest held.

It is your statutory obligation to inform the coroner in this situation and so even though it will be a difficult time for the family, they must be informed of this (and the reasoning) in a sensitive way.

You could ask the oncologist but the advice will be the same and it would just cause delays.

[Q: 4455] OnExamination 2012 - Misc

An elderly woman with a background of multiple myeloma has been started on opioid analgesia for low back pain.

Since starting opioids she has had problems with nausea and has been tried on two different agents. Her GP started a third antiemetic two weeks ago.

Her husband has noticed she seems restless and cannot keep still. He has become increasingly concerned in the last few days she has been unable to keep up with him on their walks and has generally 'slowed down'.

From the list of drugs, on which has the patient most likely been started?

- 1- Cyclizine
- 2- Domperidone
- 3- Haloperidol
- 4- Levomepromazine
- 5- Ondansetron

Answer & Comments

Answer: 3- Haloperidol

This scenario describes a patient developing drug-induced parkinsonism (DIP).

This can occur when drugs with dopamine receptor antagonist (D2) activity are initiated as antiemetics. Commonly used drugs which fall into this category include haloperidol, domperidone and metoclopramide.

Akathisia and bradykinesia are more common in drug induced parkinsonism.

Of the drugs listed here, haloperidol and domperidone have significant D2 receptor activity. Haloperidol has much greater affinity for central D2 receptors as domperidone less readily crosses the blood brain barrier.

Haloperidol is therefore much more likely to cause DIP.

[Q: 4456] OnExamination 2012 - Misc

A 51-year-old man with a history of locally advanced lung cancer presents to his GP with a short history of facial flushing and swelling and breathlessness.

He looks unwell and becomes more breathless when he lies flat to allow examination of his abdomen. At 45 degrees his JVP is elevated but his lung fields are clear. The GP phones his local hospice for advice from the duty palliative care physician.

What is the most appropriate management step to give this GP?

- 1- Breathing exercises
- 2- Oramorph to help him relax
- 3- Oxygen
- 4- Refer immediately to local oncological service
- 5- Send to hospital for CXR

Answer & Comments

Answer: 4- Refer immediately to local oncological service

The clinical features described in this scenario are typical of superior vena cava obstruction and this is a palliative care emergency.

It is most commonly caused by carcinoma of the bronchus and symptoms can come on rapidly.

If there is a high clinical suspicion the patient should be referred to the local oncology service to confirm the diagnosis and initiate management.

The other options would delay diagnosis and management.

[Q: 4457] OnExamination 2012 - Misc

You are working in a hospice for a palliative medicine team and you are called by one of

the local GPs for medication advice.

A patient of hers has recently been diagnosed with pancreatic cancer and associated severe pain. The GP started the patient on morphine sulphate modified release and an antiemetic.

Two days after starting the anti-emetic the patient came back to see the GP complaining of feeling more sleepy, blurred vision at times, constipation and a very dry mouth.

Of the choices, on which antiemetic was the patient most likely to have been started?

- 1- Cyclizine
- 2- Domperidone
- 3- Haloperidol
- 4- Metoclopramide
- 5- Ondansetron

Answer & Comments

Answer: 1- Cyclizine

Cyclizine is a commonly used antihistamine antiemetic and its primary site of action is the vomiting centre (which is rich in histamine and muscarinic cholinergic receptors).

Cyclizine has a strong affinity for muscarinic receptors and therefore anticholinergic side effects (dry mouth, drowsiness, blurred vision, constipation, etc) are common, especially in the first few days.

The other drugs listed do not have significant muscarinic receptor affinity.

[Q: 4458] OnExamination 2012 - Misc

A woman with a background of metastatic lung cancer is admitted to the Emergency department with a history of increasing drowsiness, confusion, vomiting and myoclonic jerks.

On examination she is also found to have small pupils.

On questioning her husband you find out she is on morphine sulphate modified release and cyclizine, and has recently had antibiotic treatment for a chest infection.

In view of the features from the examination and history, what is the most likely underlying aetiology for this patient's presenting problem?

- 1- Hypercalcaemia
- 2- Hyperglycaemia
- 3- Hypoxia
- 4- Morphine toxicity
- 5- Urinary tract infection

Answer & Comments

Answer: 4- Morphine toxicity

Reduced conscious level, hallucinations, vomiting, myoclonic jerks and pinpoint pupils are features of opioid toxicity.

All the options can cause an acute deterioration in a palliative care patient and should be excluded in the appropriate situations.

However this combination, and especially small pupils and myoclonic jerks, points strongly toward opioid toxicity. When opioid toxicity is diagnosed, a cause (such as renal impairment) must be sought.

[Q: 4459] OnExamination 2012 - Misc

A 73-year-old female patient has been admitted from the palliative medicine clinic for an infusion of bisphosphonate for intractable bone pain. This pain has not responded to opioids or NSAIDs and the consultant thinks bisphosphonates are indicated.

The patient undergoes an infusion of pamidronate and you are asked to review her the next day. Unfortunately she has not

noticed any improvement in her pain and asks you why this is so.

Choose the most appropriate next step?

- 1- Alter her opioids
- 2- Increase her opioids
- 3- Prescribe a further dose of pamidronate
- 4- Prescribe an alternative bisphosphonate
- 5- Reassure her benefit can be delayed by a few days

Answer & Comments

Answer: 5- Reassure her benefit can be delayed by a few days

Bisphosphonates are useful adjuncts for bone pain, especially in breast cancer and myeloma.

The patient described has not derived significant benefit from opioids so increasing or altering the dose would have been tried before and was not effective (hence her referral for specialist management).

The beneficial effect of bisphosphonates can be delayed for up to two weeks and can last for one month.

Therefore the correct response is to reassure the patient the benefit may be delayed.

[Q: 4460] OnExamination 2012 - Misc

A 67-year-old man has been diagnosed with metastatic lung cancer. He has moderate pain and has been started on morphine slow release twice a day. After a few doses he becomes nauseated and vomits on one occasion.

You are working in palliative care and are asked to advise on the most appropriate antiemetic. He has no other medical history.

Which of the following is the most appropriate first choice management option?

- 1- Cyclizine
- 2- Domperidone
- 3- Haloperidol
- 4- Ondansetron
- 5- Withdraw morphine

Answer & Comments

Answer: 3- Haloperidol

Haloperidol is a first line antiemetic for opioid-induced nausea in the palliative care setting. Its action is predominantly via D2-receptor antagonism in the chemoreceptor trigger zone (CTZ) in the brain stem.

Ninety per cent of patients taking morphine require antiemetics (morphine stimulates D2 receptors in the CTZ).

Cyclizine, although commonly used is less effective.

Domperidone also has some central D2 antagonism but less than haloperidol.

Ondansetron is a 5HT3 antagonist and is mainly used in post-chemotherapy or radiotherapy induced nausea.

Withdrawing morphine, although would resolve the problem, is not an appropriate response as the patient has moderate pain and nausea can be managed with antiemetics.

[Q: 4461] OnExamination 2012 - Misc

A 37-year-old man with advanced lymphoma is admitted to a hospice for control of a variety of symptoms. He is known to have advanced mediastinal disease.

After three days you are called to assess him as he has complained to the nurses of shortness of breath. On arrival in his room he looks unwell. He is struggling to complete sentences because of breathlessness. His venous pressure is elevated and his pulse is

120. His chest is clear with a normal percussion note.

Which is the most likely diagnosis?

- 1- Left ventricular failure
- 2- Panic attack
- 3- Pericardial effusion
- 4- Pleural effusion
- 5- Pneumothorax

Answer & Comments

Answer: 3- Pericardial effusion

Diagnosing pericardial effusions early is essential and should always be considered as a differential for breathlessness, especially in patients with mediastinal disease.

A strong clinical clue is breathlessness with raised venous pressure but normal chest examination.

Answers A, D and E would be likely to result in an abnormal chest examination.

A panic attack would not cause these examination findings (unless panic occurred on top of another condition).

[Q: 4462] OnExamination 2012 - Misc

A 35-year-old woman has been admitted to the local hospice for control of pain.

She has been diagnosed with advanced cervical cancer and has continued chemotherapy. During her prolonged admission to the hospice she is transferred to the local oncology centre for cisplatin chemotherapy. The following day she is profoundly nauseated. The staff nurse looking after this lady asks you to prescribe an antiemetic.

What is the most appropriate antiemetic for this indication?

- 1- Cyclizine

- 2- Domperidone
- 3- Haloperidol
- 4- Metoclopramide
- 5- Ondansetron

Answer & Comments

Answer: 5- Ondansetron

Ondansetron is a potent 5HT₃-receptor antagonist.

It is an especially useful antiemetic when nausea results from a massive release of serotonin (5HT) from enterochromaffin cells (for example, post-chemotherapy).

Certain chemotherapy agents (for example, cisplatin) have a high 'emesis risk' and treatment with ondansetron or other related drugs is essential.

In the United Kingdom 5HT₃ antagonists are licensed only for post-chemotherapy and post-operative nausea.

[Q: 4463] OnExamination 2012 - Misc

A 45-year-old with a history of renal cell carcinoma presents to his local Emergency department with a brief history of lethargy. He recently underwent a cycle of chemotherapy.

You take a full history and examine the patient. Following this you arrange a set of blood tests. Half an hour later you are phoned by the biochemistry laboratory and informed your patient's creatinine is 232. You check his previous results and note his creatinine for four weeks ago was 87. He is on several medications for pain and nausea.

Which of these medications should be avoided in this situation?

- 1- Cyclizine
- 2- Fentanyl
- 3- Haloperidol

- 4- Morphine
5- Paracetamol

Answer & Comments

Answer: 4- Morphine

Morphine has active metabolites which accumulate with renal impairment and can lead to opioid toxicity. Morphine should therefore be avoided in this situation.

Fentanyl is a good alternative in this situation as the same problem does not occur.

Cyclizine, haloperidol and paracetamol can all be used in renal impairment but the dose should be altered and patient monitored for side effects.

[Q: 4464] OnExamination 2012 - Misc

A 63-year-old patient with prostate cancer presents with constipation.

He was diagnosed with prostate cancer after a biopsy four months ago. Following various investigations he was diagnosed with local and distant metastases. Despite this he has remained relatively well and is able to live independently.

He has not opened his bowels for three days and has been feeling generally tired.

What is the most appropriate next step?

- 1- Blood tests, including bone profile
- 2- IV fluids
- 3- Laxatives orally
- 4- Refer to surgeons
- 5- Stop opioid

Answer & Comments

Answer: 1- Blood tests, including bone profile

Hypercalcaemia is a common problem in palliative care. It is more common in certain cancers and prostate cancer with bone

metastasis (as suggested in this scenario) is a frequent cause.

Hypercalcaemia can cause a wide variety of symptoms including constipation.

Of the options all are potentially appropriate, depending on the patient, but if there is a high likelihood of hypercalcaemia, this should be ruled out first.

[Q: 4465] OnExamination 2012 - Misc

A 48-year-old man is diagnosed with renal cell carcinoma. He presents to his local palliative medicine service with constipation.

His drug list includes morphine sulphate modified release, 40 mg twice a day.

He is assessed for the cause of his constipation and given advice on fluid intake and diet. Alongside these measures he is started on a laxative.

What would be the most appropriate initial laxative?

- 1- Docusate
- 2- Fybogel
- 3- Lactulose
- 4- Movicol
- 5- Senna

Answer & Comments

Answer: 5- Senna

Ninety per cent of patients taking morphine require a laxative.

Morphine causes constipation by enhancing intestinal ring contractions which leads to hypersegmentation which in turn impairs peristalsis.

A stimulant ('contact', 'large bowel') laxative therefore is the most logical choice for this indication. Senna is the most commonly used

laxative for this indication. Other options include danthron.

Docusate is a stool softener, Fybogel a bulk-forming agent, lactulose and Movicol are osmotic laxatives.

[Q: 4466] OnExamination 2012 - Misc

A 78-year-old woman has been diagnosed with multiple myeloma.

She has been suffering severe bone pain and has been having problems with constipation. She was started on increasing doses of slow release morphine.

Which of the following explains the mechanism of morphine-induced constipation?

- 1- Anorexia
- 2- Dehydration
- 3- Enhanced intestinal ring contractions
- 4- Nausea
- 5- Reduced bowel secretions

Answer & Comments

Answer: 3- Enhanced intestinal ring contractions

Morphine causes constipation by enhancing intestinal ring contractions. This results in hypersegmentation which in turn impairs peristalsis.

Dehydration and anorexia will also contribute but these are not the main mechanism.

Hence enhanced intestinal ring contractions is the correct answer.

Ninety per cent of patients taking morphine require a laxative and a stimulant is the best choice (such as senna).

[Q: 4467] OnExamination 2012 - Misc

A 53-year-old woman with lung cancer and secondary spine metastasis presents with severe leg pain.

She has been treated according to the WHO analgesic ladder and is currently taking morphine modified release. However despite increasing doses, her pain is not well controlled. She has also tried amitriptyline which has not helped.

You ask the local palliative medicine consultant for advice and she suggests starting gabapentin.

Choose the response which most appropriately describes the recognised primary pathway on which gabapentin is thought to work for its role in the management of neuropathic pain.

- 1- Activation of GABA inhibitory system
- 2- Enhanced descending inhibition
- 3- Inhibition of glutamate excitatory system
- 4- None of the above
- 5- Sodium channel blockade

Answer & Comments

Answer: 3- Inhibition of glutamate excitatory system

Gabapentin is a commonly used adjunctive agent for neuropathic pain. Its mechanism of action is by inhibition of glutamate excitatory neurones.

It is the only drug licensed for all types of neuropathic pain and is useful in malignant and non-malignant pain.

Four to six weeks of treatment are often needed before the patient experiences benefit.

The remaining options are pathways altered by other commonly used neuropathic agents.

[Q: 4468] OnExamination 2012 - Misc

A 67-year-old man with a history of metastatic lung cancer complains of lateral chest wall pain.

You review his notes and radiological investigations and note he has been diagnosed with lung cancer with metastatic deposits in his ribs. You take a full history and examine the patient; he complains of pain which radiates from his right lateral chest wall around to his sternum.

You think this patient's pain is a result of nerve damage and wish to start analgesia.

Which of the following is the most appropriate choice to try first in this situation?

- 1- Amitriptyline
- 2- Carbamazepine
- 3- Gabapentin
- 4- Ibuprofen and tramadol
- 5- Morphine

Answer & Comments

Answer: 4- Ibuprofen and tramadol

Nerve pain is a common problem in palliative care and can be difficult to manage.

Nerve pain often has a nociceptive opioid responsive element and hence opioids (with a combination of nonsteroidal anti-inflammatory drugs [NSAIDs]) should be tried first, and used as part of the WHO analgesic ladder.

Thus, ibuprofen and tramadol are the correct answer and not morphine.

Morphine would be tried next and then the other agents.

[Q: 4469] OnExamination 2012 - Misc

Which of the following drugs should not be prescribed for a breast-feeding mother?

- 1- Digoxin
- 2- Erythromycin
- 3- Tetracycline
- 4- Theophylline
- 5- Warfarin

Answer & Comments

Answer: 3- Tetracycline

Tetracycline should be avoided in breast-feeding mothers because of staining of the infant's teeth.

Other drugs to be avoided include amiodarone, lithium, chloramphenicol and vitamin A derivatives.

[Q: 4470] OnExamination 2012 - Misc

A 35-year-old gentleman with well controlled rheumatoid arthritis has, with his wife, been trying to conceive for 18 months. He and his wife visit you in fertility clinic.

What is the likely cause of their problem?

- 1- Chloroquine
- 2- Chronic illness reducing fertility
- 3- Leflunomide
- 4- Methotrexate
- 5- Reduced fertility due to female pelvic inflammatory disease

Answer & Comments

Answer: 3- Leflunomide

Leflunomide reduces sperm count.

Chronic illness can affect fertility; however in this case the gentleman's rheumatoid arthritis

is well controlled and therefore should not be a barrier to conception.

Chloroquine is safe in pregnancy and does not affect fertility. Its side effects include gastrointestinal disturbances and headaches.

Methotrexate does not affect fertility but should be avoided in pregnancy. Its more serious side effects are bone marrow suppression and hepatotoxicity, hence blood monitoring required.

Female related problems are the most common cause of infertility, especially pelvic inflammatory disease, secondary to infection. However in this case a good drug history will point to other causes.

[Q: 4471] OnExamination 2012 - Misc

A 22-year-old woman has come to the clinic complaining that she has had no periods for the past four months. She was always a normal weight, but has found it difficult to maintain her size since starting intensive training to run a marathon. She takes no regular medication.

On examination her BMI is 18 kg/m². Physical examination, including assessment of secondary sexual characteristics is unremarkable.

Investigations show

Haemoglobin 11.4 g/dl (11.5-16.5)

White cell count 6.9 x 10⁹/L (4-11)

Platelets 203 x 10⁹/L (150-400)

Sodium 140 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 102 µmol/l (79-118)

Albumin 40 g/l (35-50)

Alanine amino transferase 10 U/l (5-40)

Follicle stimulating hormone 15 IU/l (<20)

Thyroid stimulating hormone 2.5 mU/l (0.5-5.0)

Which of the following is the most likely diagnosis?

1- Autoimmune ovarian failure

2- Pregnancy

3- Prolactinoma

4- Secondary amenorrhoea due to weight loss

5- Thyrotoxicosis

Answer & Comments

Answer: 4- Secondary amenorrhoea due to weight loss

This lady has secondary amenorrhoea, whereby menstruation has previously occurred but has stopped for more than six months. Given she has been intensively training and has a BMI of 18, it seems most likely that she has amenorrhoea related to weight loss.

Weight loss can cause amenorrhoea, especially if rapid, BMI is less than 19 and more than 10% of body weight has been lost. The amenorrhoea is felt to be directly related to weight, but excess endorphin production may also play a part.

FSH is in the normal range, which counts against autoimmune (premature) ovarian failure; we have no signs at all that she is pregnant, and she does not report symptoms consistent with prolactinoma, such as vaginal dryness or breast leakage of milk.

Additionally her TSH is in the normal range, which rules out thyrotoxicosis.

[Q: 4472] OnExamination 2012 - Misc

A 17-year-old primigravida complains of constipation and arthralgia at 28 weeks' gestation.

A number of biochemical investigations are performed, but which of these are clinically significant?

- 1- Detectable urinary human chorionic gonadotrophin
- 2- Free thyroxine 8.9 pmol/l (9-22)
- 3- Prolactin of 1000 mU/l (<450)
- 4- Serum alkaline phosphatase of 350 iu/l (50-110)
- 5- Serum corrected calcium 2.89 mmol/l (2.2-2.6)

Answer & Comments

Answer: 5- Serum corrected calcium 2.89 mmol/l (2.2-2.6)

This patient has symptoms suggestive of hypercalcaemia, which are clinically significant.

Free thyroxine (T4) is at the lower end of the normal range which is often the case in pregnancy and thyroid-stimulating hormone (TSH) is a better guide of thyroid function.

Hyperprolactinaemia is a normal finding in pregnancy, as is detectable urinary human chorionic gonadotrophin.

It is also normal for serum alkaline phosphatase to rise by up to four times normal due to increased placental production.

[Q: 4473] OnExamination 2012 - Misc

A 51-year-old lady enquires about taking hormone replacement therapy (HRT).

Which of the following is the most compelling indication for taking HRT?

- 1- Control of flushing
- 2- Prevent Alzheimer's disease
- 3- Prevent ischaemic heart disease
- 4- Prevent osteoporosis
- 5- Reverse vaginal atrophy

Answer & Comments

Answer: 1- Control of flushing

The indications for HRT have been a matter of great debate over recent years.

Relieving the symptoms of menopause is the most compelling indication.

[Q: 4474] OnExamination 2012 - Misc

A 28-year-old female returns from a trip to Bangladesh with a fever, diarrhoea and rash. She is diagnosed with typhoid fever.

However, she has a 1-month-old infant and wishes to continue to breast feed.

Which of the following antibiotics is the most appropriate therapy for her?

- 1- Ceftriaxone
- 2- Chloramphenicol
- 3- Ciprofloxacin
- 4- Cotrimoxazole
- 5- Gentamicin

Answer & Comments

Answer: 1- Ceftriaxone

Typhoid fever is best treated with quinolones, chloramphenicol or cotrimoxazole.

However, with breast feeding chloramphenicol is relatively contraindicated as are quinolones due to potential risk even if small.

Also cotrimoxazole is safe in breast feeding except with infants less than 2 months due to possible risk of increased bilirubin.

In pregnancy or children the drug of choice is parenteral ceftriaxone.

[Q: 4475] OnExamination 2012 - Misc

A fit and healthy couple present with a three year history of first trimester recurrent miscarriages.

Which of the following tests would be the most appropriate for this couple?

- 1- Maternal and paternal karyotyping
- 2- Maternal oral glucose tolerance test
- 3- Maternal prolactin concentration
- 4- TORCH screen
- 5- Vaginal swabs for bacterial vaginosis

Answer & Comments

Answer: 1- Maternal and paternal karyotyping

Recurrent first trimester miscarriages warrant further investigation which would include karyotyping and assessment for lupus anticoagulant.

Hyperprolactinaemia may cause subfertility rather than miscarriage.

There is no evidence that gestational diabetes per se causes recurrent first trimester miscarriages.

TORCH (toxoplasmosis, other, rubella virus, cytomegalovirus, and herpes simplex) infection would be unlikely to precipitate recurrent miscarriage.

Bacterial vaginosis rather than associated with recurrent early miscarriage is associated with second trimester miscarriage and premature labour.

[Q: 4476] OnExamination 2012 - Misc

A 25-year-old female is diagnosed with polycystic ovarian syndrome and commenced on metformin.

Which of the following are recognised effects of the use of metformin in the treatment of polycystic ovarian syndrome?

- 1- Improves action of vasopressin
- 2- Improves chances of conception
- 3- Increases exercise capacity
- 4- Reduces testosterone concentration
- 5- Reduces weight

Answer & Comments

Answer: 2- Improves chances of conception

Polycystic ovarian syndrome is recognised to be a condition associated with increased insulin resistance and metformin is effective through improvements in insulin sensitivity resulting in ovulation and improvements in hormonal perturbations.

It has been shown to increase rates of conception but has no appreciable effect on weight loss.

[Q: 4477] OnExamination 2012 - Misc

Which of the following should receive treatment with varicella immunoglobulin?

- 1- A non-immune pregnant woman who is exposed to her mother who has shingles
- 2- A pregnant woman non-immune to varicella zoster (VZV) exposed to a child with chicken pox 12 days previously.
- 3- A pregnant woman previously treated with varicella zoster immunoglobulin 10 days ago who has been re-exposed to a case of chicken pox.
- 4- A pregnant woman who has no history of chicken pox but develops shingles in pregnancy
- 5- A pregnant woman with asthma taking steroids, who has had chicken pox as a child but is now exposed to her daughter who has chicken pox.

Answer & Comments

Answer: 1- A non-immune pregnant woman who is exposed to her mother who has shingles

Varicella immunoglobulin is effective if used sufficiently early in patients proven to be non-immune to VZV and in whom exposure to VZV is confirmed.

The beneficial effects may last up to three weeks following initial treatment and beyond this, it can be used again should re-exposure occur.

However, it is still important to check VZV antibodies as subclinical disease may have occurred due to its prior use.

VZV can be given up to 10 days with efficacy following exposure.

For more information on this topic please see the following guideline (RCOG):

<http://www.rcog.org.uk/files/rcog-corp/uploaded-files/GT13ChickenpoxinPregnancy2007.pdf>

[Q: 4478] OnExamination 2012 - Misc

A 31-year-old woman in her third pregnancy is receiving low molecular weight heparin (LMWH) at treatment doses due to a pulmonary embolism three months prior to conception. She is currently at 31 weeks gestation.

All fetal scans have been normal, and her blood pressure is 126/80 mmHg in the left lateral position.

Which of the following statements is correct?

- 1- Breastfeeding is not advised
- 2- Clexane treatment needs no monitoring in pregnancy
- 3- It is safe for her to receive NSAIDs perinatally

4- Prothrombin time is an indicator of anti-factor Xa activity

5- The dose of Clexane should be increased in the third trimester

Answer & Comments

Answer: 2- Clexane treatment needs no monitoring in pregnancy

Neither heparin nor warfarin are contraindications to breastfeeding.

There is no recommendation that the dose of LMWH should be increased in the third trimester.

Increases in prothrombin time and activated clotting time (ACT) are not linearly correlated with increasing LMWH anti-thrombotic activity and therefore are unsuitable and unreliable for monitoring LMWH activity.

Nonsteroidal anti-inflammatory drug (NSAID) treatment increases the risk of haemorrhage in both mother and fetus.

It is not known whether unchanged enoxaparin sodium is excreted in human breast milk. The oral absorption of enoxaparin sodium is unlikely. However, as a precaution, lactating mothers receiving enoxaparin sodium should be advised to avoid breast feeding.

for more information on this topic please see the following link to college guidelines:

<http://www.rcog.org.uk/files/rcog-corp/GTG37aReducingRiskThrombosis.pdf>

[Q: 4479] OnExamination 2012 - Misc

A 34-year-old woman comes to the Emergency department GP complaining of intermenstrual bleeding, particularly after sexual intercourse, pain on intercourse and intermittent severe right iliac fossa pain.

In the last month she was admitted to the Emergency department with suspected appendicitis but later discharged.

On examination she is pyrexial 37.9 C and there is bilateral lower abdominal tenderness. Speculum examination reveals cervicitis and mucopurulent cervical discharge.

Which of the following represents the most appropriate antibiotic regime?

- 1- Cephalexin 500 mg BD and metronidazole 400 mg PO BD for 14 days
- 2- Ceftriaxone 250 mg IM then doxycycline 100 mg BD and metronidazole 400 mg BD for 14 days
- 3- Metronidazole 400 mg PO BD for 7 days
- 4- Metronidazole 400 mg PO BD for 14 days and ciprofloxacin 500 mg BD for 14 days
- 5- Ofloxacin 400 mg BD for 7 days

Answer & Comments

Answer: 2- Ceftriaxone 250 mg IM then doxycycline 100 mg BD and metronidazole 400 mg BD for 14 days

The answer is B, ceftriaxone 250 mg IM then doxycycline 100 mg BD and metronidazole 400 mg BD for 14 days.

This patient has symptoms consistent with pelvic inflammatory disease, which may be sexually transmitted and due either to Chlamydia or gonorrhoea. Antibiotic treatment should not wait for swab or culture results and be commenced once the diagnosis is made.

Referral to a GUM clinic should be considered to arrange screening across the range of possible sexually transmitted infections.

Long term sequelae include possible tubal scarring and subfertility.

[Q: 4480] OnExamination 2012 - Misc

A 32-year-old woman presents to the clinic in a very distressed state.

She is 35 weeks pregnant with her first child. Apparently she has developed a crop of herpetic ulcers over her vulva and on further questioning her husband admitted to unprotected sex with a prostitute during a business trip. The ulcers are confirmed as containing herpes simplex virus and serology suggests that this is a primary infection.

Which of the following represents the correct management with respect to the delivery of her child?

- 1- Aciclovir cover is not recommended in any circumstances for the mother during delivery
- 2- Aciclovir is not recommended in any circumstances for the infant during the post partum period
- 3- She can be left to make up her mind about the mode of delivery
- 4- She should have a caesarean section
- 5- She should have a vaginal delivery

Answer & Comments

Answer: 4- She should have a caesarean section

The answer is D, she should have a caesarean section.

RCOG guidance is clear that when primary herpes infection occurs within six weeks of expected delivery, then caesarean delivery is the recommended course of action.

Additionally, IV aciclovir cover for mother and infant during the peri-partum period is recommended if a vaginal delivery should occur. If vaginal delivery occurs in the absence of aciclovir cover, an analysis of five available studies suggest that the neonatal infection rate may be up to 41%.

[Q: 4481] OnExamination 2012 - Misc

A 32-year-old woman comes to her 20 week visit in her first pregnancy.

You are asked to review her as she is hypertensive, with a BP of 162/102 mmHg. Her BP at booking was also elevated at 141/91 mmHg. She has no significant past medical history of note apart from having consulted the practice nurse at the surgery for weight loss counselling over the past few years.

On examination she looks well, physical examination being consistent with a 20 week pregnancy.

Investigations show

Haemoglobin 11.0 g/dl(11.5-16)

White cell count $5.1 \times 10^9/L$ (4-10)

Platelets $189 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (134-143)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 89 $\mu\text{mol/l}$ (60-120)

Glucose 5.0 mmol/l (<6.0)

Urine Blood and protein negative

Which of the following is the most appropriate anti-hypertensive medication for her?

- 1- Atenolol
- 2- Hydrochlorothiazide
- 3- Methyldopa
- 4- Ramipril
- 5- Valsartan

Answer & Comments

Answer: 3- Methyldopa

Methyldopa is the treatment of choice for hypertension in pregnancy, as it has the largest evidence base for use.

Labetalol (alpha- and β -blocker) is the most commonly used second line agent, with dihydropyridines the usual choice for patients who fail to tolerate these agents.

Angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) are not recommended for use in pregnancy because of concerns about teratogenicity, particularly with respect to abnormalities of the renal tract (second/third trimester) cardiovascular and neurological (first trimester).

As such, patients who are using ARBs or ACE inhibitors should change their medication prior even to trying to get pregnant.

[Q: 4482] OnExamination 2012 - Misc

A 50-year-old female presents with concerns related to reduced libido.

This has been causing problems with her husband as she does not feel like sex at all and she feels rather down.

In her past history she has had ovarian failure associated with a hysterectomy three years ago and is being treated with oestradiol 2 mg daily.

Which of the following would be the most appropriate treatment for this patient?

- 1- Add fluoxetine
- 2- Add norethisterone
- 3- Add testosterone patch
- 4- Increase dose of oestrogen
- 5- Use vaginal oestrogen gel

Answer & Comments

Answer: 3- Add testosterone patch

Hypoactive sexual desire disorder is well recognised in post-menopausal females as well as in patients following ovarian failure.

This may not improve despite adequate oestrogen replacement therapy as in this case and testosterone patches have been demonstrated to improve desire, activity and reduce distress.

Progestagens are not required in hysterectomised subjects and may cause a deterioration in symptoms.

[Q: 4483] OnExamination 2012 - Misc

A 26-year-old woman who is 12 weeks pregnant, presents with a concern after being exposed to her mother who has been diagnosed with facial shingles one day ago.

She was unaware of what the rash was and had examined the rash closely two days ago before her mother was diagnosed. She informs you that she is unaware of ever having chicken pox.

Which of the following is the most appropriate action that should be taken for this patient?

- 1- She should be reassured that she will not contract Varicella zoster from her mother.
- 2- She should be tested immediately for IgG antibodies to Varicella zoster
- 3- She should be treated with Varicella zoster immunoglobulin
- 4- She should immediately receive Varicella zoster vaccine
- 5- She should receive treatment immediately with aciclovir

Answer & Comments

Answer: 2- She should be tested immediately for IgG antibodies to Varicella zoster

The patient gives a very good history of exposure to Varicella zoster virus (VZV) and it is possible for her to acquire chicken pox if she is non-immune.

However, she may well have had VZV infection as a child and the most important action is first to measure IgG antibodies to VZV. If these are present no further action need be taken and the patient relatively reassured.

If she is non-immune then the patient will probably need to be treated with VZ immunoglobulin which has been shown to reduce severity and possible fetal infection.

[Q: 4484] OnExamination 2012 - Misc

An 18-year-old Asian girl was found to be pregnant after missing her last menstrual period despite her appropriate use of the oral contraceptive pill for the last two years.

She was found also to have been taking additional medication prescribed by a specialist two months ago.

Which of the following accounts for the pill failure?

- 1- Cimetidine
- 2- Erythromycin
- 3- Isoniazid
- 4- Ketoconazole
- 5- Rifampicin

Answer & Comments

Answer: 5- Rifampicin

Rifampicin is a hepatic drug-metabolising enzyme inducer.

Thus it enhances the metabolism of oral contraceptive pills, decreasing its effectiveness and resulting in pill failure.

[Q: 4485] OnExamination 2012 - Misc

Which of the following is the most appropriate anticonvulsant for the treatment of an eclamptic fit?

- 1- Diazepam
- 2- Lorazepam
- 3- Magnesium sulphate.
- 4- Phenytoin
- 5- Thiopentone

Answer & Comments

Answer: 3- Magnesium sulphate.

Refer to the important conclusions of the Collaborative Eclampsia Trial and the Cochrane Review by Duley and Gulmezoglu.

[Q: 4486] OnExamination 2012 - Misc

A 29-year-old woman is receiving subcutaneous Clexane (low-molecular weight heparin [LMWH]) for the treatment of pulmonary embolism. She is 30 weeks pregnant and develops bruising on her lower arms.

The blood pressure in the left lateral position is 125/75 mmHg.

What is the most appropriate test for this patient?

- 1- Anti factor Xa levels
- 2- APTT
- 3- Platelet count
- 4- Serum albumin
- 5- Serum potassium

Answer & Comments

Answer: 3- Platelet count

This is likely to be heparin-induced thrombocytopenia (HIT).

Long term LMWH treatment has been associated with low platelet counts and this is the test which is likely to provide you with the most information.

Clexane may cause hyperkalaemia, but this is unlikely to cause bruising.

Albumin levels may increase in pregnancy but serum albumin may be low due to haemodilution.

Activated partial thromboplastin time (APTT) is not useful in monitoring LMWH activity, although APTT may be prolonged in high dose Clexane treatment.

Factor Xa levels can be used to monitor efficacy of treatment but the suggestion of bruising here points more to HIT for which Xa levels would not be a useful guide.

[Q: 4487] OnExamination 2012 - Misc

A 29-year-old female who is 22 weeks pregnant is noted to have a blood pressure of 150/90 mmHg on three separate occasions.

Urine protein is negative.

Which of the following would be the first line treatment?

- 1- Alpha methyl dopa
- 2- Atenolol
- 3- Magnesium sulphate
- 4- Nifedipine
- 5- Salbutamol

Answer & Comments

Answer: 1- Alpha methyl dopa

Beta blockers are safe in the third trimester of pregnancy but are generally not used due to fears of intrauterine growth retardation (IUGR).

Generally one would favour labetalol in these circumstances given that there is an evidence base for its use.

Magnesium sulphate is a recognised treatment for pre-eclampsia, a condition which is not described here.

Nifedipine may be used by experienced clinicians but is currently unlicensed for this use.

There is good evidence that methyldopa is effective and safe for both mother and baby in pregnancy.

[Q: 4488] OnExamination 2012 - Misc

A 67-year-old man presents after having a urine tract infection treated and has read in a magazine that maybe it would be worth checking a PSA.

When should his PSA be checked?

- 1- Check in three days' time
- 2- Check in one week
- 3- Check in two weeks
- 4- Check on this occasion
- 5- No need to check PSA

Answer & Comments

Answer: 3- Check in two weeks

Prostate-specific antigen (PSA) concentrations can rise with problems of false positives after catheterisation and particularly urinary tract infections (UTI).

Therefore, if one has decided to check a PSA then it is recommended that this should be measured at least two weeks after a treated UTI.

[Q: 4489] OnExamination 2012 - Misc

A 56-year-old man who has presented with chest pain, has a PSA of 45 ng/ml (normal less than 4).

Which of the following statements is correct with respect to this patient's management?

- 1- An elevated PSA is a definitive test for prostate cancer

- 2- High selenium intake is related to prostate cancer
- 3- Prostate cancer is more aggressive with increasing age
- 4- Prostate cancer is typically squamous cell carcinoma
- 5- The most commonly used pathological grading system is the Gleason score

Answer & Comments

Answer: 5- The most commonly used pathological grading system is the Gleason score

Prostate-specific antigen (PSA) may be elevated in prostatitis, benign prostatic hyperplasia and prostate cancer.

High intake of animal fats is related to prostate cancer, as well as low intake of selenium.

As a rule, prostate cancer is more aggressive in younger men.

Prostate cancer is an adenocarcinoma.

The Gleason score is recommended by the American College of Pathologists. The most well differentiated tumours have a Gleason score of 2, and the most poorly differentiated a Gleason score of 10.

[Q: 4490] OnExamination 2012 - Misc

Which one of the following cutaneous lesions is associated with HIV infection?

- 1- Leucoplakia
- 2- Lichen planus
- 3- Lichen sclerosus
- 4- Plasma cell balanitis
- 5- Psoriasis

Answer & Comments

Answer: 5- Psoriasis

It occurs in 2-4% of healthy people. If pre-existing psoriasis flares up for no apparent reason or middle-aged people develop psoriasis for the first time, one should exclude underlying HIV infection in those patients.

Leucoplakia is a pre-cancerous lesion whereas oral hairy leucoplakia is a sign of immunodeficiency in an HIV positive patient.

Lichen planus, lichen sclerosus and plasma cell balanitis are not associated with HIV infection.

[Q: 4491] OnExamination 2012 - Misc

Which one of the following is an AIDS defining illness?

- 1- Anal canal warts
- 2- Extra genital molluscum contagiosum
- 3- Multidermatomal shingles
- 4- Oesophageal candidiasis
- 5- Oral candidiasis

Answer & Comments

Answer: 4- Oesophageal candidiasis

Any opportunistic infections or opportunistic malignancies are AIDS defining illnesses.

Oesophageal candidiasis is an AIDS defining illness but oral candidiasis is not.

Anal warts are not an opportunistic infection.

Extra genital molluscum contagiosum is also not an opportunistic infection but frequently occurs in symptomatic HIV positive patients.

Multidermatomal shingles is not an opportunistic infection but if it occurs in a young person HIV infection needs to be excluded.

[Q: 4492] OnExamination 2012 - Misc

A 28-year-old man with HIV presents with a five day history of feeling unwell. He is a heavy smoker.

A chest radiograph showed right upper lobe consolidation. His CD4 count was 468 cells/mm³. HIV RNA level was 90,678 copies/ml. He is not on any antiretroviral treatment.

What is the most likely diagnosis?

- 1- Bronchial carcinoma
- 2- Invasive pulmonary aspergillosis
- 3- Pulmonary tuberculosis
- 4- Pneumocystis jiroveci pneumonia (PCP)
- 5- Streptococcal pneumonia

Answer & Comments

Answer: 5- Streptococcal pneumonia

This is typical of community-acquired pneumonia. One should think of common infections rather than any opportunistic infections in HIV patients with good CD4 counts. (More than 400 cells/mm³ is not immunocompromised.)

It is not a typical history for bronchial carcinoma as the history was short and radiographic changes were not typical of bronchial carcinoma.

Invasive pulmonary aspergillosis is unlikely in a patient with good CD4 count. Pulmonary tuberculosis typically causes cavitating lesions in a patient with a good CD4 count.

PCP commonly occurs in patients with CD4 count of less than 200 cells/mm³ and chest radiograph shows bilateral infiltrates from the hila without any effusion or lymphadenopathy.

[Q: 4493] OnExamination 2012 - Misc

Which one of the following is an oncogenic virus?

- 1- Hepatitis A
- 2- Human papilloma virus 6 (HPV 6)
- 3- Human papilloma virus 11 (HPV 11)
- 4- Human papilloma virus 16 (HPV 16)
- 5- Varicella zoster virus (VZV)

Answer & Comments

Answer: 4- Human papilloma virus 16 (HPV 16)

HPV 16 is oncogenic and causes squamous cell carcinomas in the oral cavity, cervix, anus and penis.

Hepatitis A is not an oncogenic virus, as it does not cause chronic infection or cancer.

HPV 6 and 11 typically cause the majority of benign warts.

VZV causes chicken pox and herpes zoster.

Reference:

Yoganathan K, Patel RN, Maitland N, McManus TJ, Calman FM, Pozniak A. Carcinoma of the penis in an HIV positive patient. *Genitourin Med.*1995 Feb; 71 (1): 41-2.

[Q: 4494] OnExamination 2012 - Misc

A 34-year-old homosexual Caucasian man developed jaundice two months after taking a combination of antiretroviral drugs.

He admitted that he had had several episodes of unprotected sex with several casual male partners. His liver function showed raised bilirubin with normal transaminases and alkaline phosphatase.

What is the most likely cause of his jaundice?

- 1- Acute hepatitis B
- 2- Alcoholic hepatitis

- 3- Atazanavir
- 4- Efavirenz
- 5- Nevirapine

Answer & Comments

Answer: 3- Atazanavir

Atazanavir causes hyperbilirubinaemia with normal transaminases and alkaline phosphatase (mimicking Gilbert's syndrome).

Acute hepatitis B is unlikely with normal transaminases and alkaline phosphatase.

A mild to moderate rise in transaminases and alkaline phosphatase occurs in alcoholic hepatitis.

Efavirenz can cause acute hepatitis with raised levels of transaminases.

Nevirapine causes acute hepatitis where transaminases are raised several-fold.

[Q: 4495] OnExamination 2012 - Misc

Which of the following is a sign of immunodeficiency in the mouth?

- 1- Gingivitis
- 2- Herpes labialis
- 3- Leucoplakia
- 4- Oral hairy leucoplakia
- 5- Oral wart

Answer & Comments

Answer: 4- Oral hairy leucoplakia

Oral hairy leucoplakia is a sign of immunodeficiency. It is due to reactivation of Epstein-Barr virus infection.

Gingivitis is not a sign of immunodeficiency.

Leucoplakia is not a sign of immunodeficiency but it is a precancerous lesion.

Herpes labialis is due to herpes simplex infection, which causes 'cold sores' in immunocompetent patients and chronic herpes labialis in immunocompromised patients.

Oral warts can occur in healthy people. They are due to HPV infection usually due to benign types, 6 and 11.

[Q: 4496] OnExamination 2012 - Misc

A 32-year-old African woman with HIV presents with a two week history of greenish, frothy, itchy vaginal discharge.

What is the most likely cause of her discharge?

- 1- Candida albicans infection
- 2- Chlamydia infection
- 3- Foreign body
- 4- Gonorrhoea infection
- 5- Trichomonas vaginalis infection

Answer & Comments

Answer: 5- Trichomonas vaginalis infection

Trichomonas vaginalis causes itchy, frothy, greenish vaginal discharge.

Candida albicans causes a white, curdy, itchy vaginal discharge.

Chlamydia and gonorrhoea do not cause itchy, frothy vaginal discharge and both can be asymptomatic.

Foreign body causes foul smelling vaginal discharge.

[Q: 4497] OnExamination 2012 - Misc

A 39-year-old Caucasian man with symptomatic HIV disease developed multiple painless umbilicated papular lesions on his face.

What is the most likely cause of his skin lesions?

- 1- Cytomegalovirus (CMV)
- 2- Epstein Barr virus (EBV)
- 3- Human herpes virus (HHV) 8
- 4- Human papilloma virus (HPV 16)
- 5- Pox virus

Answer & Comments

Answer: 5- Pox virus

Multiple painless umbilicated papular lesions are typical of molluscum contagiosum and are caused by pox virus.

CMV does not cause painless papular lesions.

EBV causes Burkitt's lymphoma, non-Hodgkin's lymphoma and primary brain lymphomas.

HHV 8 is strongly associated with Kaposi's sarcoma.

HPV 16 is associated with squamous cell carcinomas in cervix, penis, anus and oral cavity.

Reference:

Bain S, Yoganathan K. *Physical Signs for the General Practitioner. Case 51. Molluscum contagiosum. Dental update. 2008; 68.*

Yoganathan K, Patel RN, Maitland N, McManus TJ, Calman FM, Pozniak A. *Carcinoma of the penis in a HIV positive patient. Genitourin Med. 1995 Feb; 71 (1): 41-2.*

[Q: 4498] OnExamination 2012 - Misc

A 46-year-old homosexual HIV positive man presents with a two week history of weakness of his right arm and leg.

Examination reveals right hemiparesis and left cerebellar signs. CT scan shows white matter lesions in the left cerebellar region and left temporoparietal area. There is no midline shift or surrounding oedema.

Which one of the following is most likely to be found in his cerebrospinal fluid (CSF)?

- 1- Positive cytomegalovirus (CMV) PCR
- 2- Positive Epstein-Barr virus (EBV) PCR
- 3- Positive herpes simplex virus (HSV) PCR
- 4- Positive human herpes virus (HHV) 8 PCR
- 5- Positive JC PCR

Answer & Comments

Answer: 5- Positive JC PCR

Multifocal lesions in left cerebellar and temporoparietal white matter areas without any mass effect or surrounding oedema are most likely to be due to progressive multifocal leucoencephalopathy (PML).

JC virus causes PML in immunocompromised patients especially when the CD4 count is below 100 cells/mm³.

CMV polymerase chain reaction (PCR) may be found in CMV encephalitis. It is clinically not a typical feature of CMV encephalitis.

Positive EBV PCR indicates primary brain lymphoma where CT scan often shows significant mass effect with surrounding oedema.

HSV PCR may be found in HSV encephalitis which commonly affects temporal lobes in patients with good CD4 count.

HHV 8 PCR is usually associated with Kaposi's sarcoma.

[Q: 4499] OnExamination 2012 - Misc

A 54-year-old woman is referred to the chest clinic by the GP with a history of a non-productive cough. She is severely troubled by her symptoms often waking at night. She is a smoker with a 25-pack year history.

According to the current British Thoracic Society guidelines, at least how long must

symptoms be present to be defined as a chronic cough and investigated as such?

- 1- 3 weeks
- 2- 4 weeks
- 3- 8 weeks
- 4- 3 months
- 5- 4 months

Answer & Comments

Answer: 3- 8 weeks

In epidemiological studies 16% of the United Kingdom population reported a persistent cough.

For the purposes of the BTS guidelines, cough is a forced expulsive manoeuvre against a closed glottis with a characteristic sound.

Acute cough is defined as one lasting less than three weeks. A chronic cough is defined as one lasting over eight weeks. There is a grey area between three to eight weeks and this includes post-viral coughs.

There are several serious conditions that may present with an isolated cough including neoplasm, infection (for example, TB), and interstitial lung disease.

In those with a normal chest x ray, reflux disease, asthma syndromes and rhinitis should be considered.

British Thoracic Society guidelines.

[Q: 4500] OnExamination 2012 - Misc

A 45-year-old lady with a history of depression presented to the Emergency department drowsy.

Her repeat prescription says she is taking diazepam and dosulepin, and the ambulance crew say that she has taken an overdose of her medication. Her BP is 140/80 mmHg,

pulse 130 bpm, respiratory rate 7 per minute and O₂ sats 98% on air.

Which of the following is the most appropriate next action?

- 1- Give flumazenil
- 2- Give naloxone
- 3- Obtain an ECG
- 4- Refer for urgent haemodialysis
- 5- Start N-acetylcysteine infusion

Answer & Comments

Answer: 3- Obtain an ECG

This is a tricky case and will catch those who go for the first answer they see that is reasonable.

The urge is quickly to treat the drowsy patient with respiratory depression with some sort of antidote, but there needs to be a diagnostic step first.

Tricyclic antidepressants can cause fatal arrhythmias and seizures which are very difficult to manage.

An electrocardiogram (ECG) would immediately indicate if there is a risk of significant tricyclic toxicity by showing a wide QRS complex or abnormal axis deviation.

[Q: 4501] OnExamination 2012 - Misc

A cohort study of 7,500 patients aimed to find out whether the use of olive oil in cooking has an impact on cardiovascular disease.

Approximately half the patients used olive oil in cooking and half used animal fat.

Which of these is a disadvantage of a cohort study?

- 1- It is not possible to measure the incidence/risk of a disease
- 2- They are not suitable when exposure to risk factors is rare

- 3- They are susceptible to recall bias; there is a differential ability of patients to remember exposure to a risk factor
- 4- They can only provide information about one outcome
- 5- When the outcome of interest is rare a very large sample size is needed.

Answer & Comments

Answer: 5- When the outcome of interest is rare a very large sample size is needed.

A cohort study takes a group of individuals and follows them for a period of time, the aim being to study whether the exposure to a particular aetiological factor has any effect on the incidence of disease.

As such they are relatively time consuming and expensive to perform. Advantages include being able to study exposure factors that are rare and being less susceptible to recall bias than case-control studies.

They are also able to measure the incidence/risk of a disease.

Results are usually expressed as the relative risk of developing the disease given exposure to the aetiological factor.

[Q: 4502] OnExamination 2012 - Misc

A 32-year-old man is referred to the dyslipidaemia clinic for markedly elevated plasma triglycerides.

As measured by his GP they were elevated at 6.5 mmol/l.

On clinical examination which of the following signs is most consistent with isolated hypertriglyceridaemia?

- 1- Corneal arcus
- 2- Kayser-Fleischer rings
- 3- Lipaemia retinalis
- 4- Xanthelasma

5- Xanthochromia

Answer & Comments

Answer: 3- Lipaemia retinalis

The answer is option C, lipaemia retinalis.

Lipaemia retinalis is an association between hypertriglyceridaemia and a pale pink milky appearance to the retinal vessels or even to the retina itself.

Xanthelasma and corneal arcus are associated with hypercholesterolaemia, and xanthochromia is yellowing of the vision.

Kayser-Fleischer rings are associated with Wilson's disease.

Triglycerides themselves are noted as a cardiovascular risk factor both in epidemiological and interventional studies.

[Q: 4503] OnExamination 2012 - Misc

Regarding the epidemiology of infections, which of the following statements is true?

- 1- Diphtheria has been eradicated in most parts of the world.
- 2- Polio has been eradicated in most parts of the world.
- 3- Resistant vivax malaria is a major problem in Kenya.
- 4- Tetanus has been eradicated in most parts of the world.
- 5- The AIDS epidemic seems to be declining worldwide.

Answer & Comments

Answer: 2- Polio has been eradicated in most parts of the world.

Falciparum is the major resistance problem in sub-Saharan Africa.

Most vivax is chloroquine sensitive, though resistant strains are appearing in New Guinea and Indonesia.

Diphtheria is still prevalent in many parts of the world.

An upsurge in polio is now nearing eradication.

Tetanus is still common.

AIDS is increasing inexorably.

[Q: 4504] OnExamination 2012 - Misc

An 85-year-old patient presents with recurrent falls and a fracture of the distal ulna.

Which of the following statements is correct?

- 1- Bone fractures attributable to vitamin D deficiency are due to bone density
- 2- Low vitamin D levels are not associated with muscle weakness
- 3- The toxic levels of vitamin D occur at approximately twice the therapeutic dose
- 4- Vitamin D deficiency in the elderly is rare
- 5- Vitamin D replacement reduces the incidence of fractures in the elderly

Answer & Comments

Answer: 5- Vitamin D replacement reduces the incidence of fractures in the elderly

The clue is in the question.

Vitamin D deficiency in the elderly is common, especially in the housebound and those in residential and nursing homes, with an overall frequency of 17% in women aged 85 and over.

Vitamin D deficiency is associated with muscle weakness, as well as osteomalacia, and fractures among elderly people with vitamin D deficiency are often not attributable to reduced bone density.

Vitamin D replacement (800 IU daily) with calcium, has been shown to reduce falls and fractures by 47% compared with controls who received calcium only.

The correct dose of vitamin D replacement should be 800 IU.

Lowest doses at which adverse events have been observed with vitamin D replacement are 200 nmol/l, which equates to a daily dose of 40,000 IU.

BMJ 2005;330:524-6.

[Q: 4505] OnExamination 2012 - Misc

A 22-year-old female presents with a month history of episodic, brief visual loss affecting the right eye.

Over the last one year she had gained a considerable amount of weight. Examination reveals a BMI of 35, with bilateral optic disc swelling, worse on the right and small retinal haemorrhages on the right.

What is the most likely diagnosis?

- 1- Benign intracranial hypertension (BIH)
- 2- Craniopharyngioma
- 3- Graves' ophthalmopathy
- 4- Optic neuritis
- 5- Sagittal sinus thrombosis

Answer & Comments

Answer: 1- Benign intracranial hypertension (BIH)

This is a classic description of BIH.

Drugs such as tetracyclines, the oral contraceptive or pregnancy may be contributory.

[Q: 4506] OnExamination 2012 - Misc

Following a road traffic accident, a patient is

brought by ambulance to the Emergency department.

The primary survey reveals an open fracture of the right femur, which is bleeding profusely.

In terms of his cardiovascular physiology, what is the likely response to this blood loss?

- 1- Cardiac output is increased because of increased stroke volume and decreased heart rate
- 2- Heart rate is increased because of increased vagal stimulation of the sinoatrial node
- 3- Stroke volume is decreased because of hypovolaemia
- 4- Total peripheral resistance is increased due to a decreased sympathetic output
- 5- Venous return is increased because of decreased sympathetic output to the venous system

Answer & Comments

Answer: 3- Stroke volume is decreased because of hypovolaemia

The compensation mechanisms to sudden hypovolaemia include:

Cardiac output (CO) can increase, decrease, or stay the same ($CO = HR \times SV$). In this clinical scenario, it is likely that HR will increase, but stroke volume may decrease due to the hypovolaemia.

Heart rate (HR) can increase due to decreased (parasympathetic) vagal stimulation and enhanced sympathetic stimulation with adrenaline.

Total peripheral resistance can increase due to increased sympathetic drive. This causes peripheral vasoconstriction and preserves blood flow to essential organs, such as the brain, heart and kidneys.

Venous return increases if sympathetic output increases, and this is related to the peripheral vasoconstriction. Less blood can pool in the peripheral vessels so it is transported back to the central circulation quickly. This increases venous return and maximises stroke volume.

[Q: 4507] OnExamination 2012 - Misc

A 62-year-old woman presents with a one year history of worsening bilateral, anterior knee pain. The pain is increased by climbing stairs. Both knees are stiff for five to 10 minutes in morning. There is no history of knee swelling. The pain is partially controlled by paracetamol 1 g up to four times a day. She has a history of diabetes, and angina.

On examination, she is overweight. There is crepitus and during active and passive movement of both knees. There is no knee effusion. A recent knee x ray shows joint space narrowing in the medial tibio-femoral joint.

What is the next step in her management?

- 1- Acupuncture
- 2- Oral NSAIDs
- 3- Rest
- 4- Topical NSAIDs
- 5- Transcutaneous electrical nerve stimulation (TENS)

Answer & Comments

Answer: 4- Topical NSAIDs

This lady has osteoarthritis.

NICE guidelines recommend formulating individualised management plans for patients with osteoarthritis.

Behavioural change, such as exercise, weight loss and suitable footwear should be encouraged. Comorbidities which compound

the effect of osteoarthritis symptoms should be identified and their treatment optimised.

Paracetamol and/or topical NSAIDs (for knee or hand OA) should be offered before considering oral NSAIDs.

If symptoms are not controlled with the above strategies, oral NSAIDs or COX-2 inhibitors (but not etoricoxib) can be used. A proton pump inhibitor should be co-prescribed. The lowest effective dose should be prescribed for the shortest period possible. If the patient is already taking low-dose aspirin, an alternative analgesic should be considered.

Treatments which are not recommended include rubefacients, intra-articular hyaluronan, electro-acupuncture and chondroitin or glucosamine products.

Adjuvants which can be used include opioid analgesics, topical capsaicin and intra-articular corticosteroids.

Application of heat or cold packs, or TENS, can be considered if other strategies are ineffective. Manipulation and stretching can be helpful, particularly for hip osteoarthritis. Bracing/joint supports can be used for patients with biomechanical joint pain or instability.

Patients should be referred for joint surgery if they have already been offered all of the core treatments or if they have refractory joint symptoms which have a substantial impact on their quality of life.

If there is a clear history of mechanical locking, referral for arthroscopic lavage and debridement should be considered.

[Q: 4508] OnExamination 2012 - Misc

A 52-year-old man returns for repeat endoscopy. He was last scoped some six months earlier after persistent indigestion, upon which both duodenal ulceration and

Helicobacter was found. He underwent eradication therapy, but has been suffering worse indigestion, particularly over the past four to six weeks.

On examination his BP is 132/72 mmHg, his pulse is 70 and regular. He has mild epigastric tenderness.

Investigations show

Haemoglobin 10.9 g/dl(13.5-17.7)

White cell count $7.2 \times 10^9/L$ (4-11)

Platelets $240 \times 10^9/L$ (150-400)

Serum Sodium 143 mmol/l (135-146)

Serum Potassium 4.0 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

Serum gastrin 850 pg/ml(<200)

Repeat endoscopy: extensive duodenal ulceration.

Which of the following is the most appropriate next step in his management?

- 1- Calcium stimulation test
- 2- CT abdomen
- 3- Omeprazole 40 mg
- 4- Partial gastrectomy
- 5- Secretin stimulation test

Answer & Comments

Answer: 5- Secretin stimulation test

This patient's gastrin is moderately elevated, levels above 1,000 are strongly indicative of a gastrinoma. Unless there is concomitant high dose PPI therapy, at a level of 850 this patient should be subject to stimulation testing.

Secretin is the first choice, and a rise of greater than 200 is a pointer towards a gastrinoma as the underlying diagnosis. It would be sensible to perform the secretin first, prior to attempting pancreatic imaging.

He should not be committed to high dose PPI therapy until gastrinoma has been ruled out.

[Q: 4509] OnExamination 2012 - Misc

A 52-year-old Afro-Caribbean gentleman is diagnosed with hypertension after having three blood pressure measurements greater than 160/100 mmHg.

On examination his BMI is 24, and he looks well. There is no significant past medical history of note.

According to the NICE guidelines, which of the following is the most appropriate to prescribe first line for this patient?

- 1- Amlodipine
- 2- Atenolol
- 3- Diltiazem
- 4- Ramipril
- 5- Valsartan

Answer & Comments

Answer: 1- Amlodipine

Patients of African origin are more likely to have low renin hypertension. This means that they are more likely to respond to initial therapy with either a calcium antagonist or diuretic, usually a thiazide.

Thiazides and beta blockers have been implicated in a meta-analysis as being associated with increased risk of developing insulin resistance, but given his BMI is in the normal range this is unlikely to be a significant problem.

In contrast those patients of Caucasian origin who tend to have higher levels of renin respond much more readily to angiotensin-converting enzyme (ACE) inhibition, or if they fail to tolerate an ACE inhibitor because of cough, to an angiotensin receptor blocker. For these patients, ACE inhibition is seen by NICE as the first line treatment.

Combination therapies were designed originally around the ABCD guidelines from

the British Hypertension Society, but because of the analysis which suggested increased risk of diabetes when beta blockade is combined with a thiazide, the combination of these two is no longer recommended.

Following the ASCOT study however, the ACE inhibitor calcium antagonist combination has been the one preferred by many clinicians.

<http://www.nice.org.uk/nicemedia/pdf/CG34fullguideline.pdf>

[Q: 4510] OnExamination 2012 - Misc

Which of the following statements is the principal argument made by proponents of making commerce in human organs for legal use?

- 1- A person's heirs have the right to earn money by selling the deceased's organs.
- 2- Commercialisation is not ethically preferable to the gift model of organ donation.
- 3- It is an ethical trade in a capitalistic society
- 4- Shortages or surpluses would be eliminated.
- 5- There is already an active "black market" in transplantable organs.

Answer & Comments

Answer: 4- Shortages or surpluses would be eliminated.

Although particularly controversial the arguments for commercial organ donation suggest that surpluses or deficits in organs would be eliminated and that the current black market in this resource associated with the inherent exploitation of the poor would be resolved.

However it is unethical to exploit live donors in impoverished countries as may happen currently.

[Q: 4511] OnExamination 2012 - Misc

A 45-year-old gentleman has noticed reduced libido for the past two months, since losing his job.

He is having trouble sleeping, often waking early, and has lost weight due to a reduced appetite. His wife reports that he has been more argumentative than normal, especially in the morning when she is leaving for work.

What psychiatric diagnosis does he have?

- 1- Adjustment disorder
- 2- Bipolar disorder
- 3- Depression
- 4- Depressive anxiety neurosis
- 5- Generalised anxiety disorder

Answer & Comments

Answer: 1- Adjustment disorder

Adjustment disorder occurs within three months of an identifiable stressor and lasts six months from the withdrawal of the stressor. The patient will show either distress in excess of that expected or a disruption of their day to day life.

The criteria for diagnosing generalised anxiety disorder are anxiety/tension, occasionally accompanied by physical symptoms, on more days than not for more than six months. It is more a diagnosis of exclusion however, as it may be due to prescription medication or another psychiatric illness. It is part of the anxiety neuroses.

Anxiety neurosis is a major condition, affecting one in seven Britons.

It includes

Generalised anxiety disorder

Obsessive compulsive disorder

Panic disorder and

Post-traumatic stress.

The neurosis can be defined according to the chief symptom - depression, obsession, anxiety.

Patients show maladaptive psychological symptoms not due to organic cause and out of proportion to the precipitating stress. Underlying psychiatric illness should always be sought, especially depression.

Anxiety disorders can be treated with selective serotonin reuptake inhibitors (SSRIs) or monoamine oxidase inhibitor (MAOI).

Benzodiazepines and beta blockers can be used on a PRN basis for patients who suffer with panic attacks.

Cognitive behavioural therapy can also be of help.

To make a diagnosis of depression symptoms must be present almost everyday for at least two weeks.

Symptoms of depression are those of

Anhedonia (lack of enjoyment in daily life)

Sleeplessness (usually early waking)

Loss of concentration

Loss of appetite and weight loss

Loss of libido

Mood swings (particularly worse in the morning and often associated with feelings of guilt or worthlessness)

Psychomotor retardation or agitation and

Suicidal ideation.

Suicidal thoughts must always be checked for when diagnosing depression, to maintain patient's safety.

Bipolar disorder is depression with episodes of mania.

[Q: 4512] OnExamination 2012 - Misc

A 45-year-old male presents with a longstanding history of hypertension.

Investigations show a urea of 10.2 mmol/L (2.5-7.5) and a creatinine of 150 µmol/L (60-110).

Which one of the following would suggest a diagnosis of acute glomerulonephritis?

- 1- 24 hour urinary protein excretion of 0.8g
- 2- Dyslipidaemia
- 3- RBC casts in urinary sediment
- 4- Shrunken glomeruli on renal biopsy
- 5- Unilaterally smaller kidney

Answer & Comments

Answer: 3- RBC casts in urinary sediment

Casts containing erythrocytes (red cell casts) are an indication of renal bleeding and are typically found when there is acute glomerular inflammation caused by glomerulonephritis or vasculitis.

Answers A, B, D, and E are non-specific and do not suggest an acute glomerulonephritis.

[Q: 4513] OnExamination 2012 - Misc

A 32-year-old female presents with headaches. She has a severe frontal and occipital headache which is present as soon as she wakes in the mornings. She had given birth to a baby boy one month previously and has not been feeling well since.

Examination revealed bilateral blurring of the optic discs with a pupil sparing third nerve palsy on the right.

What is the most likely diagnosis?

- 1- Brainstem CVA
- 2- Herpes simplex encephalitis
- 3- Meningococcal meningitis

- 4- Sagittal sinus thrombosis
5- Sphenoidal wing meningioma

Answer & Comments

Answer: 4- Sagittal sinus thrombosis

Patients with a hypercoagulable state (pregnancy) and papilloedema with neurological signs should be investigated for cerebral venous thrombosis.

Patients may present with a seizure or hysteria and may be mistaken for a psychiatric disorder.

Cranial nerve 3, 4 and 6 involvement suggests a cavernous sinus thrombosis.

Isolated cortical venous sinus thrombosis may give rise to focal neurology.

The diagnosis is made by MRI and the condition may be underdiagnosed.

[Q: 4514] OnExamination 2012 - Misc

A 52-year-old man with a diagnosis as a child of coeliac disease had been asymptomatic despite poor dietary compliance.

He presents with a one month history of intermittent, colicky, central abdominal pain and 3 kilogram weight loss and positive faecal occult bloods.

What is the most appropriate investigation?

- 1- Anti-endomysial antibody.
- 2- Colonoscopy.
- 3- CT scan of abdomen.
- 4- Distal duodenal biopsy.
- 5- Small bowel enema.

Answer & Comments

Answer: 2- Colonoscopy.

New-onset weight loss with positive faecal occult bloods and central abdominal pain in a

52-year-old man must be assumed to be colonic carcinoma until proven otherwise.

Colonoscopy is the best way to check for this and would also demonstrate inflammatory bowel disease if present.

If the colonoscopy were negative, then an OGD would be needed to check for upper gastrointestinal malignancy.

[Q: 4515] OnExamination 2012 - Misc

Depression is seen after damage to which part of the brain?

- 1- Amygdala
- 2- Left frontal
- 3- Left temporal
- 4- Right frontal
- 5- Right temporal

Answer & Comments

Answer: 2- Left frontal

Temporal lobe damage typically causes problems with memory and is the most epileptogenic lobe of the brain.

The amygdala is involved in emotional processing particularly fear.

Bilateral damage can result in the so-called Kluver-Bucy syndrome.

[Q: 4516] OnExamination 2012 - Misc

Functional psychiatric illness rather than an organic brain disorder is suggested by which of the following?

- 1- A family history of major psychiatric illness
- 2- Clouding of consciousness
- 3- Impaired short term memory
- 4- No previous history of psychiatric illness

- 5- Onset for the first time at the age of 55 years

Answer & Comments

Answer: 1- A family history of major psychiatric illness

This question tries to establish typical features of psychiatric disease such as depression/schizophrenia rather than organic brain disease, for example, dementia.

Loss of short term memory and older age are more typical of organic brain disease; however a family history is especially associated with depressive illness and schizophrenia.

[Q: 4517] OnExamination 2012 - Misc

A 26-year-old woman presents with three episodes of collapse over the last nine months. She says that she feels hungry to the pit of her stomach before these episodes occur, sweaty and tremulous.

On examination her BMI is 31, her BP is 142/82 mmHg, pulse is 64. She is obese but there are no other abnormal findings.

Which of the following findings would most point towards an insulinoma?

- 1- Co-existent hypertension
- 2- Co-existent thyroid mass
- 3- Low levels of glucagon
- 4- Weight gain of 5 kg over the past six months
- 5- Weight loss of 5 kg over the past six months

Answer & Comments

Answer: 4- Weight gain of 5 kg over the past six months

Co-existent hypertension may occur because of weight gain, but is not particularly indicative of an insulinoma.

Indeed, hypertension in the context of multiple endocrine neoplasia (MEN) may indicate a pheochromocytoma, which of course is associated with MEN2 where insulinomas do not occur.

A thyroid mass may indicate medullary thyroid carcinoma which is also associated with MEN2 not MEN1. If anything, glucagon levels are more likely to be elevated than reduced.

[Q: 4518] OnExamination 2012 - Misc

A 35-year-old woman presents with shortness of breath, palpitations and anxiety.

The episodes have been occurring over three years, but are worse recently. The episodes occur at stressful periods and are also related to difficult tasks at work. There is no history of drug or alcohol abuse.

What is the most appropriate pharmacological management for this patient?

- 1- Alprazolam
- 2- Chlorpromazine
- 3- Clomipramine
- 4- Paroxetine
- 5- Promethazine

Answer & Comments

Answer: 4- Paroxetine

In anxiety disorder, benzodiazepines are effective for short term stabilisation but should not be used for longer than two to four weeks.

Cognitive behavioural therapy is suggested to be particularly effective, though it is not widely available.

The use of benzodiazepines is associated with poorer outcomes. In longer term management, they are inferior to cognitive behavioural therapy and antidepressants.

NICE guidelines recommend first line pharmacological management with citalopram or escitalopram and suggest avoiding antipsychotics and sedative antihistamines.

[Q: 4519] OnExamination 2012 - Misc

A 45-year-old man has a history of progressive weakness for five weeks. He had particular difficulty getting out of the bath.

On examination there was severe truncal and proximal limb weakness, without wasting or fasciculation.

Tendon reflexes, plantar responses and sensation were all normal.

The vital capacity was 1.8L.

What is the most likely diagnosis?

- 1- Cervical myelitis
- 2- Guillain-Barre syndrome
- 3- Polio
- 4- Polymyositis
- 5- Syringobulbia

Answer & Comments

Answer: 4- Polymyositis

The presentation of myopathy is characterised by proximal weakness with normal reflexes and sensation and the absence of fasciculations.

Polymyositis is the commonest cause of inflammatory muscle disease in people under 50-years-old (inclusion body myositis is the commonest in those over 50-years-old).

[Q: 4520] OnExamination 2012 - Misc

A 70-year-old woman is diagnosed with anaplastic thyroid cancer.

What is the most likely consequence of this cancer?

- 1- Brain metastases
- 2- Hypercalcaemia from bony metastases
- 3- Liver metastases
- 4- Lung metastases
- 5- Upper airways obstruction

Answer & Comments

Answer: 5- Upper airways obstruction

Anaplastic thyroid cancer carries a very poor prognosis with the vast majority (~90%) having local invasion (cervical lymph glands) and local infiltration (particularly the trachea) at diagnosis.

Lung and bone metastases are common at presentation (~ 50%).

Upper airways obstruction frequently requires tracheostomy.

[Q: 4521] OnExamination 2012 - Misc

An 80-year-old male presents with a brief history of weakness and giddiness following an episode of diarrhoea.

He has been taking bendroflumethiazide for the last three years.

On examination his pulse is 100 beats per minute with a blood pressure of 130/80 mmHg (lying) and 100/70 mmHg (standing).

Investigations reveal:

Sodium 120 mmol/L(137-144)

Potassium 5.5 mmol/L(3.5-4.9)

Urea 13 mmol/L(2.5-7.5)

Creatinine 130 µmol/L(60-110)

Random plasma glucose 13 mmol/L(<11.1)

What is the most likely cause of the hyponatraemia?

- 1- Bendroflumethiazide
- 2- Diarrhoea
- 3- Hyperglycaemia
- 4- Inappropriate secretion of antidiuretic hormone
- 5- Renal tubular acidosis

Answer & Comments

Answer: 5- Renal tubular acidosis

The patient has diabetes as reflected by the elevated random glucose, has hyponatraemia, renal impairment and mild hyperkalaemia which appears to have been precipitated following diarrhoea.

Hypoadrenalism is unlikely as he has hyperglycaemia and the hyperglycaemia would itself be expected to cause a dehydration and hence hypernatraemia.

This sort of picture in an elderly male with diabetes is typical of hyporeninaemic hypoaldosteronism - type IV RTA - and could be exacerbated both by the diarrhoea and by the diuretic.

It is unlikely that the diarrhoea alone has caused the hyponatraemia.

[Q: 4522] OnExamination 2012 - Misc

A 45-year-old man has noted pain in his right knee for several years. There is no joint swelling. As he moves about during the day, the pain decreases.

The underlying disease process is probably which of the following?

- 1- Osteoarthritis
- 2- Osteochondroma
- 3- Osteomalacia

- 4- Osteopetrosis
- 5- Osteoporosis

Answer & Comments

Answer: 1- Osteoarthritis

Osteoarthritis is one of the most common joint diseases, and its incidence is increasing with the age and weight of the population. It presents with pain, commonly affecting the knees, hips and small joints of the hand. Pathogenesis involves the localised loss of cartilage, with remodelling of adjacent bone. The associated pain is exacerbated by exercise and relieved by rest, although in advanced disease rest and night pain can develop. There may also be joint stiffness, typically in the morning or after rest. Diagnosis is often late, and treatment is usually aimed at reducing pain and improving function rather than targeting the disease process.

Osteoporosis is characterised by progressive deterioration of bone micro-architecture, with associated decrease in bone mineral density. It is typically asymptomatic until the complicated by fracture when pain is exacerbated by movement.

Osteochondroma is a benign tumour of cartilage, which can be located about the knee. However, they commonly present in adolescence as a painless lump which grows with the bone. Pain is not a predominant symptom.

Osteomalacia is caused by a deficiency of vitamin D and presents with widespread bone pain and tenderness (especially lower back and hips), muscle weakness and lethargy,

Osteopetrosis, an uncommon inherited metabolic disorder, leads to 'brittle bones' that predispose to fractures. Isolated joint pain is not typically an associated feature.

This question tests your understanding of disease prevalence, and the relative

importance of certain symptoms and signs in differentiating disease. Patients rarely present with the classical textbook descriptions of symptoms. From the options given above osteoarthritis is the MOST LIKELY diagnosis.

[Q: 4523] OnExamination 2012 - Misc

An 18-year-old male is diagnosed with Becker's muscular dystrophy.

Which of the following statements concerning the genetics of the condition is correct?

- 1- His brothers will all be affected
- 2- His daughters' sons will have a 50% chance of having the disease
- 3- His daughters will have a 50% chance of being carriers
- 4- His sons' children will have a 50% chance of having the disease
- 5- His sons will be carriers of the condition

Answer & Comments

Answer: 2- His daughters' sons will have a 50% chance of having the disease

Becker's muscular dystrophy is an X linked condition and so 50% of males will be affected in a family.

His sons will get the X chromosome from his wife and so will not be carriers but all his daughters will be carriers.

However, his daughters' sons will consequently have a 50% chance of inheriting the disease as all his daughters are carriers and there is a one in two chance (50:50) of passing the gene on to their sons.

On the other hand his sons who are not affected do not pass on the condition.

[Q: 4524] OnExamination 2012 - Misc

A 50-year-old man is admitted to hospital with a third attack of renal stones in the last six months. He suffers from Crohn's disease and has previously had a limited small bowel resection, but his disease is now quiescent.

On examination his BP is 115/72 mmHg, his BMI is 19.5 kg/m², and he has a midline scar consistent with a previous laparotomy.

Investigations:

Haemoglobin 12.0 g/dl (13.5-17.7)

White cell count 5.9 x 10⁹/L (4-11)

Platelets 172 x 10⁹/L (150-400)

Serum sodium 139 mmol/l (135-146)

Serum potassium 3.9 mmol/l (3.5-5)

Creatinine 133 µmol/l (79-118)

24 hour urinary oxalate excretion Increased

Which of the following is likely to be the most effective and appropriate intervention?

- 1- Increase fluid intake
- 2- Reduce dietary calcium intake
- 3- Reduce intake of offal
- 4- Start bendroflumethiazide
- 5- Start furosemide

Answer & Comments

Answer: 1- Increase fluid intake

Reducing intake of offal is most helpful at reducing urate excretion; foods such as chocolate, rhubarb and nuts are high in oxalate. One contributor to this patient's increased oxalate excretion is undoubtedly his partial small bowel resection, and increasing dietary calcium intake decreases urinary oxalate excretion.

Therefore the most effective and appropriate intervention from those given is to increase his oral fluid intake significantly.

[Q: 4525] OnExamination 2012 - Misc

You are currently working in the local hospice on a palliative medicine rotation.

A patient is admitted from the GP with a one week history of fatigue, lethargy, itch and constipation. On arrival he appears drowsy and weak. On further questioning of his wife you note he has been confused at times and has no appetite.

On examination he looks dehydrated with a pulse of 60. Pupils look normal sized. Respiratory rate is 16 and the rest of the examination is unremarkable.

You review his letters from the oncologist and discover the underlying diagnosis is metastatic renal cell cancer. He has also been complaining of hip pain for the last eight weeks.

What is the most likely cause of this patient's deterioration?

- 1- Hypercalcaemia
- 2- Hyperglycaemia
- 3- Hypokalaemia
- 4- Morphine toxicity
- 5- Urinary tract infection

Answer & Comments

Answer: 1- Hypercalcaemia

Hypercalcaemia of malignancy is a palliative care emergency and should be considered in all patients presenting with acute deterioration.

It occurs in approximately 10% of patients with cancer and usually in those with disseminated cancer. Typical features include altered consciousness, fatigue, general aches, dehydration, constipation, bradycardias and other arrhythmias.

Morphine toxicity is unlikely here in view of the normal sized pupils and respiratory rate.

A severe urinary tract infection (with sepsis) could account for the symptoms but you would expect a tachycardia.

Therefore the most likely answer to fit with the clinical features is hypercalcaemia.

[Q: 4526] OnExamination 2012 -
Emergency Medicine

Which of the following reactions is involved in the metabolism of paracetamol under normal conditions?

- 1- Acetylation
- 2- Conjugation to glucuronic acid
- 3- Conjugation to glutathione
- 4- Cytochrome p450 dependent oxidation
- 5- Hydrolysis

Answer & Comments

Answer: 2- Conjugation to glucuronic acid

Paracetamol is conjugated to glucuronic acid and sulphate under normal conditions.

In overdose these processes become saturated and the drug is then conjugated with glutathione.

If the glutathione supply is depleted then a toxic metabolite is formed.

[Q: 4527] OnExamination 2012 -
Emergency Medicine

A 30-year-old male metal worker was referred to the plastic surgery department with a three day history of a painful right index finger.

On examination he has a red, swollen index finger with a small puncture wound on the tip of his index finger. All movements in his finger were normal. An x ray of his finger is shown.

What is the diagnosis?

- 1- Foreign body
- 2- Mallet finger
- 3- Osteomyelitis of the distal phalanx
- 4- Paronychia
- 5- Undisplaced fracture of the distal phalanx

Answer & Comments

Answer: 1- Foreign body

The radiographs of the patient's finger shows a foreign body which is most likely a metal splinter embedded beneath the nail bed. This has most likely given rise to a local infection. Option A is the correct answer.

The management would entail antibiotics and removal of the foreign body as a source of infection.

Osteomyelitis is an infection of bone. x Ray features of osteomyelitis do not usually become apparent until several weeks after the onset of disease. x Ray features may include bone remodelling, sclerosis, and thickening. Option C is not the correct answer.

No fractures are present on the radiograph; hence option E is not the correct answer.

Paronychia is a soft tissue infection around a fingernail. Although a paronychia is possible given the clinical findings, the x ray demonstrates a foreign body as the cause of the symptoms. Option D is incorrect.

Mallet finger is loss of extensor tendon continuity at the distal interphalangeal joint (DIPJ) which causes the joint to rest in an abnormally flexed position. Mallet finger cannot be the diagnosis as all finger movements were normal. Option B is not the correct answer.

[Q: 4528] OnExamination 2012 -
Emergency Medicine

A 40-year-old gentleman attends the emergency department with a stroke affecting his left arm and leg.

A CT scan confirms that there is a right CVA. Carotid scanning shows occlusion of the right carotid and 50% stenosis on the left.

What is the best course of action?

- 1- Bilateral carotid endarterectomy
- 2- Discharge and GP follow up
- 3- Discharge and outpatient follow up
- 4- Urgent carotid endarterectomy on the left

5- Urgent carotid endarterectomy on the right

Answer & Comments

Answer: 3- Discharge and outpatient follow up

This patient has a symptomatic carotid on the right but has an occlusion so the risk of future stroke is minimal from this carotid.

There is no benefit from carotid endarterectomy.

[Q: 4529] OnExamination 2012 -
Emergency Medicine

A 40-year-old man is admitted to the Emergency department after being involved in a house fire.

He is extremely drowsy but you notice on examining him that he seems well perfused, with his cheeks looking almost pink. His BP is 100/60 mmHg and his pulse is 95 and regular. Blood gas analysis reveals a CO level of 12% and a metabolic acidosis with a pH of 7.15.

Which of the following is the most appropriate next intervention?

- 1- Hyperbaric oxygen
- 2- IV mannitol
- 3- IV sodium bicarbonate
- 4- 100% oxygen by mask
- 5- Nebulised salbutamol

Answer & Comments

Answer: 4- 100% oxygen by mask

The answer is 100% oxygen by mask.

Hyperbaric oxygen is recommended by some countries including the US, although because of a lack of randomised control evidence it is not standard practice in the UK as there appears to be no significant improvement in outcome as opposed to high flow oxygen alone.

Sodium bicarbonate is not indicated, and IV mannitol is only used if there is suspicion of cerebral oedema.

Key to prognosis is removal from the source of carbon monoxide as quickly as possible, and instigation of high flow oxygen treatment. At a level of 12%, long term psychological disturbance or memory loss is possible.

[Q: 4530] OnExamination 2012 -
Emergency Medicine

A 22-year-old male is admitted wheezing with a respiratory rate of 35/min, a pulse of 120 beats per min, blood pressure 110/70 mmHg, peak expiratory flow rate <50% predicted.

The emergency medical services have administered salbutamol 5 mg (twice), ipratropium 0.5 mg and face mask oxygen.

His arterial blood gas reveals:

pH 7.42 (7.36-7.44)

paCO₂ 5.0 kPa (4.7-6.0)

paO₂ 22 kPa (11.3-12.6)

Base excess -2 mmol/l (+/-2)

SpO₂ 98

Which of the following is the most appropriate action for this man?

- 1- Chest x ray
- 2- Intensive care referral
- 3- Ipratropium
- 4- Magnesium 1-2 g
- 5- Oxygen 35 %

Answer & Comments

Answer: 4- Magnesium 1-2 g

This patient fits the criteria for life-threatening asthma. A normal PaCO₂ in an asthmatic is a warning of impending respiratory failure as the patient becomes too tired to ventilate adequately.

Initial treatment has been given: β_2 -agonists should be administered as soon as possible, preferably nebulised driven by oxygen. Repeat doses should be given at 15-30 minute intervals, or continuous nebulisation can be used where there is inadequate response to bolus therapy. Nebulised ipratropium bromide should be added for patients with acute severe or life threatening asthma, or those with a poor initial response. Its addition produces significantly greater bronchodilation than a β_2 -agonist alone. Oxygen should be given to maintain saturations at 94-98%. Patients with saturations less than 92% on air should have an ABG to exclude hypercapnia. However, starting treatment should not be delayed to do the ABG. Initially high-flow oxygen is used, and then weaned to maintain adequate saturations. Unless you suspect COPD there isn't a need to be cautious with oxygen therapy. This gentleman is receiving adequate ipratropium and oxygen, and repeating/increasing these are unlikely to help the situation markedly.

Failure to respond to the above treatment steps warrants the use of intravenous magnesium sulphate (or aminophylline, but this is not an option here). Magnesium has been shown to result in bronchial smooth muscle relaxation.

Intensive care is indicated for patients with severe acute or life threatening asthma who are failing to respond to therapy. Consider it in patients with deteriorating peak flow, persisting or worsening hypoxia, hypercapnia, acidosis, exhaustion or altered conscious state. All patients who are transferred to an intensive care unit should be accompanied by a doctor who can intubate if necessary. This would be considered if this gentleman fails to respond to magnesium, and in a clinical setting you would want to discuss him with your ITU colleagues whilst the magnesium was being given.

Chest radiographs are not indicated unless you suspect pneumothorax or consolidation,

or there is life-threatening asthma, a failure to respond to treatment or a need for ventilation.

As an additional point, steroids reduce mortality, relapses, subsequent hospital admission and requirement for β_2 -agonists. The earlier they are given in the attack, the better the outcome. A dose of 40-50mg should therefore be given once oxygen and nebuliser therapy has been established. This should be continued for 5 days, or until recovery, and can then be stopped abruptly unless the patient has taken long-term oral corticosteroids.

[Q: 4531] OnExamination 2012 -
Emergency Medicine

A 38-year-old man experiences sudden deterioration after being admitted to the intensive care unit because of severe pneumococcal pneumonia and septic shock.

Arterial blood gas analysis reveals:

pH 7.2(7.36-7.44)

paO₂ 12 kPa(10-13.3)

paCO₂ 4.7 kPa(4.7-6)

HCO₃⁻ 16 mmol/l (20-28)

Which one of the following changes will be found in this patient at this time?

- 1- Hyperventilation leading to the increase in CO₂ concentration
- 2- Increase production of HCO₃⁻
- 3- Increased renal excretion of HCO₃⁻
- 4- Raised hydrogen ions level in the blood
- 5- Respiratory acidosis

Answer & Comments

Answer: 4- Raised hydrogen ions level in the blood

This patient has a metabolic acidosis with a low HCO₃ and a normal PaCO₂.

In a patient with low pH, increased hydrogen ion concentration will be found.

He is not hyperventilating as indicated by the normal PaCO₂.

In chronic acidosis, for instance in advanced renal impairment, bicarbonate levels may be supplemented to buffer the raised hydrogen ion concentrations. Bicarbonate supplementation in this situation needs to be undertaken with great care as it may worsen an intracellular acidosis.

[Q: 4532] OnExamination 2012 - Emergency Medicine

An anxious 22-year-old female with a high respiration rate has the following arterial blood gas results:

pH 7.27 (7.36-7.44)

pCO₂ 2.6KPa (4.7-6.0)

Base deficit -12 mmol/l

What is the interpretation of the acid-base status?

- 1- Combined metabolic and respiratory acidosis
- 2- Combined metabolic and respiratory alkalosis
- 3- Metabolic acidosis with some compensatory respiratory alkalosis
- 4- Respiratory acidosis with some compensatory metabolic alkalosis
- 5- Respiratory alkalosis with some compensatory metabolic acidosis

Answer & Comments

Answer: 3- Metabolic acidosis with some compensatory respiratory alkalosis

This patient has a metabolic acidosis as evidenced by a pH of 7.27 and a base deficit, which is a marker of the extent of acidosis.

The low CO₂ is a reflection of the physiological respiratory compensation which is attempting to normalise pH by clearing the acidic gas CO₂.

[Q: 4533] OnExamination 2012 - Emergency Medicine

A 24-year-old man presented twelve hours after an overdose of dihydrocodeine 1.2 g and paracetamol 30 g.

He had pinpoint pupils, a Glasgow coma scale (GCS) score of 14 and a blood pressure of 100/60 mmHg.

Which one of the following is the most appropriate management?

- 1- 500 ml of 10% glucose intravenously over four hours.
- 2- Intravenous flumazenil.
- 3- Intravenous N-acetylcysteine.
- 4- Intravenous naloxone.
- 5- Oral activated charcoal.

Answer & Comments

Answer: 3- Intravenous N-acetylcysteine.

This patient's GCS is reasonable and the opiate-like effects seem minimal (no evidence of respiratory depression).

However, this patient has received a hefty dose of paracetamol conferring a high risk of hepatic toxicity. The 12 hour delay makes the absorptive effects of charcoal limited and although it would be useful as gastric emptying may be delayed it is not as important in this patient as the paracetamol antidote.

Even though the paracetamol level is not provided, he should be treated with N-acetylcysteine without delay.

[Q: 4534] OnExamination 2012 - Emergency Medicine

A 76-year-old man with a recent history of

cerebral haemorrhage is admitted with a cough, worsening breathlessness and right pleuritic chest pain. He is also mildly pyrexial.

His ventilation-perfusion scan reveals several areas of ventilation/perfusion mismatches in the right lower zone.

What is the most appropriate line of management?

- 1- Aspirin therapy
- 2- Antibiotics
- 3- Inferior vena cava (IVC) filter
- 4- Low molecular weight heparin treatment
- 5- Warfarin treatment

Answer & Comments

Answer: 3- Inferior vena cava (IVC) filter

This patient has a pulmonary embolism (PE) following a recent haemorrhagic stroke.

The risk of rebleeding into the stroke area is too high with anticoagulation.

The best action would be percutaneous insertion of IVC filter which may be as effective as anticoagulation. It is used in cases where anticoagulation is contraindicated or in those in whom anticoagulation alone fails.

[Q: 4535] OnExamination 2012 - Emergency Medicine

Which of the following would be expected to reduce maternal mortality when given in eclampsia?

- 1- Insulin and dextrose infusion
- 2- Low dose dopamine infusion
- 3- Magnesium infusion
- 4- Phenytoin infusion
- 5- Salbutamol infusion

Answer & Comments

Answer: 3- Magnesium infusion

Magnesium has been shown significantly to reduce maternal mortality in eclampsia and a favourable outcome may also be expected in pre-eclampsia.

None of the other agents has been associated with a reduced mortality in eclampsia.

[Q: 4536] OnExamination 2012 - Emergency Medicine

A 44-year-old immigrant from Romania presents to the emergency department with a headache, neck stiffness and gradually worsening confusion over the past few days.

You understand from his relative that he also has a chronic cough and has lost a significant amount of weight recently.

On examination he is pyrexial 37.8°C, his BP is 134/72 mmHg, pulse is 85 and regular. He has marked neck stiffness and photophobia.

Investigations show:

Haemoglobin 12.0 g/dl (13.5-17.7)

White cell count $11.5 \times 10^9/L$ (4-11)

Platelets $238 \times 10^9/L$ (150-400)

ESR 80 mm/hr(<10)

Sodium 133 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 94 $\mu\text{mol/l}$ (79-118)

CXR fibrosis suspicious of tuberculosis

Lumbar puncture lymphocytic pleocytosis

PCR positive for tuberculosis

Which of the following is the correct duration of four drug therapy?

- 1- 1 month
- 2- 2 months
- 3- 6 months
- 4- 10 months
- 5- 18 months

Answer & Comments

Answer: 2- 2 months

All of the other options are incorrect because no matter what the location of infection, two months of four drug therapy is the standard, before reducing this to two drugs.

The exception is multi-drug resistant tuberculosis, where patients are commenced initially on five or more agents.

[Q: 4537] OnExamination 2012 -
Emergency Medicine

Which of the following is correct in malignant hyperpyrexia?

- 1- A mortality rate of 20% may be expected
- 2- Elevation of serum creatine kinase and myoglobinuria is diagnostic
- 3- Muscle biopsy may be histologically normal
- 4- The only available specific treatment is sodium dantrolene, which has a neutral pH
- 5- The predisposing gene is thought to be on chromosome 9

Answer & Comments

Answer: 3- Muscle biopsy may be histologically normal

Malignant hyperpyrexia (MH) is characterised by increased temperature and muscle rigidity during anaesthesia, which results from abnormal skeletal muscle contraction and increased metabolism.

The predisposing gene is thought to be on chromosome 19, close to the gene for the ryanodine/dihydropyridine receptor complex.

Known triggering agents include the volatile anaesthetic agents and suxamethonium. Patients show different sensitivity to the triggering agents and the reaction can be delayed by several hours.

Intravenous dantrolene (up to 10 mg/kg) is the only available specific treatment and care must be taken when administering as the solution has a pH of 9-10.

The prognosis of malignant hyperpyrexia is good when the appropriate treatment is instigated early, mortality being less than 5% (prior to dantrolene the mortality was 80%).

Serum creatine kinase elevation and myoglobinuria are suggestive but not diagnostic of MH. Myoglobin and creatine kinase are both known to increase after giving suxamethonium to normal patients.

Contracture tests using caffeine and halothane are the investigations of choice.

Muscle biopsies may appear histologically normal.

[Q: 4538] OnExamination 2012 -
Emergency Medicine

A 38-year-old policeman presents to the Emergency department with a painful left ring finger after attempting to arrest a criminal.

On examination his finger is flexed at the distal interphalangeal joint (DIPJ) and he is unable to straighten it actively. Passively the DIPJ can be moved freely. Examination of the rest of the hand is normal.

An x ray of his finger is shown.

What is the diagnosis?

- 1- Central slip rupture
- 2- DIPJ dislocation
- 3- Flexor digitorum superficialis rupture
- 4- Mallet finger
- 5- Volar plate injury

Answer & Comments

Answer: 4- Mallet finger

The x ray demonstrates a small avulsion fracture from the base of the distal phalanx

where the extensor tendon attaches. Given the clinical findings and x ray the diagnosis is mallet finger, therefore option D is a correct answer.

A flexion force on the tip of the extended finger jolts the DIPJ into flexion. This may result in a stretching or tearing of the tendon substance or an avulsion of the tendon's insertion on the dorsal lip of the distal phalanx base.

A DIPJ dislocation is not likely as the joint moves freely on examination and is congruent on the x ray.

Flexor digitorum superficialis is a flexor of the proximal interphalangeal and metacarpophalangeal joint. Hence option C is incorrect.

The central slip is part of the extensor expansion on the dorsal aspect of the finger. The central slip inserts onto the middle phalanx as it causes extension at the proximal interphalangeal joint (PIPJ). Hence, option A is incorrect.

The volar plate forms part of the floor of the joint capsule at the PIPJ. It separates the joint from the flexor tendons. Dislocations at the PIPJ can damage this structure and lead to pain, swelling and reduced movement at the PIPJ. In the above case the pathology is at the DIPJ, hence option E is incorrect.

[Q: 4539] OnExamination 2012 - Emergency Medicine

A 75-year-old lady attends the Emergency department with amaurosis fugax on the left.

Carotid scanning shows stenosis of 80% on the right and 90% on the left.

What is the best course of action?

- 1- Bilateral carotid endarterectomy
- 2- Discharge and GP follow up
- 3- Discharge and outpatient follow up
- 4- Urgent carotid endarterectomy on the left

- 5- Urgent carotid endarterectomy on the right

Answer & Comments

Answer: 4- Urgent carotid endarterectomy on the left

Amaurosis fugax describes a temporary loss of vision.

The eyesight then improves and becomes normal over about 15-30 minutes. It is caused by a blockage in the blood vessels at the back of the eye.

These patients are at increased risk of future stroke from the ipsilateral carotid artery.

[Q: 4540] OnExamination 2012 - Emergency Medicine

A 75-year-old lady attends the Emergency department with a stroke affecting her left arm and leg.

A CT scan confirms that there is a right CVA. Carotid scanning shows stenosis of 80% on the right and 90% on the left.

What is the best course of action?

- 1- Bilateral carotid endarterectomy
- 2- Discharge and GP follow up
- 3- Discharge and outpatient follow up
- 4- Urgent carotid endarterectomy on the left
- 5- Urgent carotid endarterectomy on the right

Answer & Comments

Answer: 5- Urgent carotid endarterectomy on the right

Although there is limited information available in this case, there is probably an indication for intervention in this patient. Carotid artery atherosclerosis is an important cause of ischaemic stroke. The left-sided neurological signs in this patient indicate the symptomatic carotid is on the right side.

Carotid endarterectomy has been established as an effective treatment for both symptomatic patients and asymptomatic patients who are shown to have carotid artery stenosis. It reduces the risk of disabling stroke or death by 48% in a person with severe symptomatic carotid stenosis (>70%) who has had a TIA. The peri-operative risk of disabling stroke or death is approximately 3%. Current UK guidelines recommend endarterectomy for symptomatic patients with greater than 70% stenosis, based on the North American Symptomatic Carotid Endarterectomy Trial which showed clear benefit. The endarterectomy should be performed as soon as the patient is fit for surgery, preferably within two weeks of a TIA.

The benefit is marginal for symptomatic patients with 50-69% stenosis, but may be greater in male patients. NICE recommends these patients are also considered for endarterectomy. There is significantly less benefit for asymptomatic patients, even those with greater than 60% stenosis. Patients with less than 50% stenosis should not be considered for carotid surgery.

Recurrent stenosis can occur in 1-20% of patients following endarterectomy, and re-operation is needed in 1-3% of cases. Ipsilateral strokes occur in 9% of patients following endarterectomy, and 26% of those treated with medical management alone (within 2 years).

All patients with suspected non-disabling stroke or TIA who are considered as candidates for carotid endarterectomy should have carotid imaging within 1 week.

Carotid endarterectomy is also indicated following a non-disabling stroke. However, if the patient has had a disabling stroke there is no real benefit in them undergoing the procedure.

Carotid stenting is increasingly being used as an alternative to endarterectomy. This is a less

invasive revascularisation strategy, and uses an embolic protection device. There seems to be a similar early risk of death or stroke, and similar long-term benefits. Risk is higher in elderly patients, possibly due to vascular tortuosity and calcification. The procedure is currently indicated in selected cases, such as restenosis.

* please note for this explanation we have used the North American Symptomatic Carotid Endarterectomy Trial (NASCET) criteria, as opposed to the European Carotid Surgery Trialists' Collaborative Group (ECST) criteria. See NICE guidelines for the difference - carotid imaging reports will state which criteria are being used.

[Q: 4541] OnExamination 2012 -
Emergency Medicine

A 25-year-old male presents after being bitten on the hand by a terrier. The wound appears deep and is associated with swelling.

After the wound is cleaned and he has received tetanus immunisation, which of the following antibiotic regimes would be most appropriate for this patient?

- 1- Co-amoxiclav oral
- 2- Doxycycline oral
- 3- Flucloxacillin oral
- 4- Penicillin G IM
- 5- Trimethoprim oral

Answer & Comments

Answer: 1- Co-amoxiclav oral

The use of prophylactic antibiotics in dog bites is controversial although evidence supports their use in deep wounds, bites to the hands and signs of infection.

The antibiotic of choice would be oral Augmentin.

[Q: 4542] OnExamination 2012 -
Emergency Medicine

A patient has just received intravenous ceftazidime. He immediately becomes flushed and wheezy, with a blood pressure of 80/40 mmHg.

Which of the following is the most appropriate immediate management for this patient?

- 1- Chlorphenamine 10 mg IV
- 2- Epinephrine 0.2 ml of 1:1000 IV
- 3- Epinephrine 0.5 mg IV
- 4- Epinephrine 0.5 mg i.m.
- 5- Hydrocortisone 100 mg IV

Answer & Comments

Answer: 4- Epinephrine 0.5 mg i.m.

Immediate treatment of anaphylaxis includes cessation of whatever caused it.

Then give oxygen, fluids and adrenaline/epinephrine 0.5 mg intramuscularly or subcutaneously.

Checking concentrations of adrenaline is very important especially in high pressure situations. Intravenous adrenaline is potentially hazardous unless diluted appropriately.

[Q: 4543] OnExamination 2012 -
Emergency Medicine

A 17-year-old girl presents following an overdose of paracetamol, her parents having found her with empty packets of paracetamol. She states that she has taken 100 tablets, three hours earlier.

Which is the most appropriate step in this patient's management?

- 1- Administer oral activated charcoal 50 g
- 2- Give N-acetylcysteine (NAC) intravenously
- 3- Measure plasma paracetamol concentration in one hour

4- Take no action

5- Transfer to young person's psychiatric unit immediately

Answer & Comments

Answer: 3- Measure plasma paracetamol concentration in one hour

This is a tricky question especially because in clinical practice this is rarely a black and white situation. The current UK guidelines state that NAC should be given if the plasma level taken at least four hours following ingestion is above the treatment line on the standard nomogram.

Knowing the timing of paracetamol tablet ingestion is therefore crucial for calculating whether treatment with the antidote N-acetylcysteine (NAC) is needed. It can take some time to swallow a substantial number of tablets, and the start of ingestion should be used if all tablets were taken within a period of an hour. If the tablets took longer than an hour to ingest you should treat as a staggered overdose.

The critical investigations in paracetamol overdose are appropriate timed serum paracetamol concentration, liver function (including prothrombin time or INR) and renal function. Prognosis is worse if any of these are abnormal at presentation. Paracetamol concentration should be measured between four and sixteen hours after ingestion of a single dose (i.e. over less than an hour). This allows the standard nomogram to be used to allow the patient's risk to be determined. Values obtained less than four hours cannot be interpreted because absorption is not yet complete. Values taken after sixteen hours may be high because acute liver injury delays paracetamol metabolism, or falsely reassuring. If paracetamol concentration is negative after twenty-four hours and liver and renal function is normal, there is low risk of serious harm.

Activated charcoal given within an hour of overdose can reduce absorption, but is unlikely to be useful if given over an hour following tablet ingestion.

Treatment for patients who have ingested a potentially lethal dose of paracetamol is the antidote N-acetylcysteine which is a sulphhydryl donor. It is given intravenously in three sequential infusions, based on the patient's body weight. Decisions to use it are based on assessment of the risk of serious liver damage, using the standard treatment nomogram. It works by replenishing glutathione stores. The efficacy declines from about eight hours after overdose, so it is important not to delay treatment beyond eight hours in patients who may have taken a lethal dose, even if the paracetamol level is not known.

In general, NAC is safe but it commonly causes nausea when given intravenously. It can also precipitate anaphylactoid reactions, more commonly in women, patients with asthma and those with a personal or family history of drug allergy. The risk of anaphylactoid reaction is also increased in patients with lower serum paracetamol concentrations.

As it has only been three hours since this patient ingested the paracetamol, the correct management plan is to wait one hour to check her serum level and give NAC if appropriate using the treatment nomogram.

Taking no action is not appropriate in this situation, and could lead to serious consequences including death. Psychiatric evaluation is of course needed but only after the patient is treated medically.

[Q: 4544] OnExamination 2012 - Emergency Medicine

A 60-year-old male is brought to casualty in the early hours of the morning after being found unconscious in the street.

On examination, he was drowsy but localised to painful stimuli. There was no evidence of head injury or meningism.

Investigations revealed:

Sodium 134 mmol/l (137-144)

Potassium 4.0 mmol/l (3.5-4.9)

Urea 4.0 mmol/l (2.5-7.5)

Creatinine 80 µmol/l (60-110)

Glucose 4.5 mmol/l (3.0-6.0)

Chloride 100 mmol/l (95-107)

Bicarbonate 25 mmol/l (20-28)

Plasma osmolality 385 mosmol/kg (278-305)

What is the most likely explanation for his presentation?

- 1- Diazepam poisoning
- 2- Ethanol poisoning
- 3- Methanol poisoning
- 4- Phenobarbitone poisoning
- 5- Phenytoin poisoning

Answer & Comments

Answer: 2- Ethanol poisoning

This man is intoxicated.

He has a normal acid base balance, slight hyponatraemia reflecting dilution, and very high osmolality reflecting the presence of ethanol.

Methanol would produce an acidosis.

Diazepam is not an osmolyte nor would the other agents produce this picture.

[Q: 4545] OnExamination 2012 - Emergency Medicine

Which one of the following is a recognised treatment option in poisoning?

- 1- Ethanol for isopropyl alcohol poisoning
- 2- Glucagon for cocaine poisoning

- 3- Methylene blue for cyanide poisoning
- 4- N-acetylcysteine in paraquat poisoning
- 5- Pralidoxime in sarin (nerve gas) poisoning

Answer & Comments

Answer: 5- Pralidoxime in sarin (nerve gas) poisoning

Sarin is an organophosphorus. Pralidoxime reactivates acetyl cholinesterase enzyme. It should be used in the first few hours.

Ethanol reduces the formation of toxic metabolites produced after ingestion of methanol and ethylene glycol, but not isopropyl alcohol.

Glucagon is used in symptomatic β -blocker overdose.

N-acetylcysteine is used in paracetamol overdose.

Methylene blue is the antidote for serious methaemoglobinaemia.

[Q: 4546] OnExamination 2012 - Emergency Medicine

A 30-year-old man presents to the Emergency department with a history of drug overdose.

He is known to be repeatedly admitted with similar episodes of self-harm. On this occasion he is drowsy and has prominent hypersalivation.

Which of the following agents, found on his person, is the likely cause?

- 1- Chlormethiazole
- 2- Cocaine
- 3- Dosulepin
- 4- L-dopa
- 5- Solvent cannister

Answer & Comments

Answer: 1- Chlormethiazole

Hypersalivation is seen with:

Parasympathomimetic agents

Insecticides

Arsenic

Strychnine

Chlormethiazole

Clozapine

and others.

Solvent abuse may cause an acneiform rash around the buccal cavity.

Cocaine abuse leads to hypertension and nasal septum perforation.

The other agents are anticholinergic and would cause dry mouth in overdose.

[Q: 4547] OnExamination 2012 - Emergency Medicine

A 50-year-old man returns to your clinic three weeks after Botox treatment for horizontal forehead furrows. He now complains that his eyebrows are drooping (eyebrow ptosis).

What is the cause of his complaint?

- 1- Increased forehead skin laxity
- 2- Paralysis of corrugators
- 3- Paralysis of frontalis
- 4- Paralysis of procerus
- 5- Paralysis of zygomaticus major

Answer & Comments

Answer: 3- Paralysis of frontalis

Botox is a neurotoxin derived from the bacteria, Clostridium botulinum.

It blocks neuromuscular transmission inhibition of acetylcholine release at the presynaptic membrane. The end result is that the muscle contraction is inhibited.

The action of Botox is not permanent because collateral axonal sprouting establishes new neuromuscular junctions, restoring muscle function.

Botox does not affect skin laxity, hence option A is wrong.

Corrugator and procerus are both muscles that depress the eyebrow, therefore paralysis of these muscles would cause the opposite to eyebrow ptosis, hence options B and D are wrong.

Zygomaticus major elevates and retracts the angle of mouth and does not affect the eyebrows, hence option E is wrong.

Frontalis is a quadrilateral muscle found on the forehead that elevates the eyebrows; hence paralysis of this muscle can lead to eyebrow ptosis.

[Q: 4548] OnExamination 2012 - Emergency Medicine

A 19-year-old girl presents with an overdose of paracetamol.

Which of the following statements is correct?

- 1- Acetylcystine should routinely be given if the presentation is within the first 12 hours of overdose
- 2- Because she is over the age of 6, she is unlikely to develop significant toxicity
- 3- Hospitalisation will be needed for at least five days
- 4- Liver function tests should be monitored
- 5- The mortality in those with an AST of >350 IU/l is 4%

Answer & Comments

Answer: 4- Liver function tests should be monitored

Treatment with N-acetylcysteine (NAC) is given according to a standard nomogram. NAC

may be useful up to 36 hours following ingestion.

Children under the age of 6 are unlikely to develop significant toxicity, but adolescents have a higher incidence of toxic plasma levels following ingestion, and a higher incidence of abnormal aspartate transaminase (AST) >1000 IU/l.

Even after serious hepatotoxicity, the mortality rate is under 0.5%.

The occasional patient may require liver transplantation.

[Q: 4549] OnExamination 2012 - Emergency Medicine

A 75-year-old lady attends the Emergency department with dizziness and fainting. She has fully recovered. Neurological examination is normal.

Carotid scanning shows stenosis of 80% on the right and 90% on the left.

What is the best course of action?

- 1- Bilateral carotid endarterectomy
- 2- Discharge and GP follow up
- 3- Discharge and outpatient follow up
- 4- Urgent carotid endarterectomy on the left
- 5- Urgent carotid endarterectomy on the right

Answer & Comments

Answer: 3- Discharge and outpatient follow up

Dizziness and fainting are not associated with transient ischaemic attacks (TIAs) or strokes and as such are not an indication for urgent carotid intervention.

However, she has bilateral, asymptomatic, severe ICA stenoses.

The choices are bilateral endarterectomy, bilateral stenting or best medical treatment. This is an individual decision to be made after an outpatient discussion.

[Q: 4550] OnExamination 2012 -
Emergency Medicine

A 50-year-old gentleman attends the Emergency department with weakness affecting his left arm and leg.

Carotid scanning shows 70% stenosis of the right carotid artery.

Which of the following statements is correct?

- 1- Carotid endarterectomy should be performed
- 2- Carotid endarterectomy should not be performed
- 3- Carotid stenting is associated with lower rates of stroke than surgery
- 4- Carotid stenting is proven to be safer than carotid endarterectomy
- 5- Carotid stenting should be performed

Answer & Comments

Answer: 1- Carotid endarterectomy should be performed

There is an indication for intervention in this patient. Carotid artery atherosclerosis is an important cause of ischaemic stroke. The left-sided neurological signs in this patient indicate the symptomatic carotid is on the right side.

Carotid endarterectomy has been established as an effective treatment for both symptomatic patients and asymptomatic patients who are shown to have carotid artery stenosis. It reduces the risk of disabling stroke or death by 48% in a person with severe symptomatic carotid stenosis (>70%) who has had a TIA. The peri-operative risk of disabling stroke or death is approximately 3%. Current UK guidelines recommend endarterectomy for symptomatic patients with greater than 70% stenosis, based on the North American Symptomatic Carotid Endarterectomy Trial which showed clear benefit. The endarterectomy should be performed as soon

as the patient is fit for surgery, preferably within two weeks of a TIA.

The benefit is marginal for symptomatic patients with 50-69% stenosis, but may be greater in male patients. NICE recommends these patients are also considered for endarterectomy. There is significantly less benefit for asymptomatic patients, even those with greater than 60% stenosis. Patients with less than 50% stenosis should not be considered for carotid surgery

Recurrent stenosis can occur in 1-20% of patients following endarterectomy, and re-operation is needed in 1-3% of cases. Ipsilateral strokes occur in 9% of patients following endarterectomy, and 26% of those treated with medical management alone (within 2 years).

All patients with suspected non-disabling stroke or TIA who are considered as candidates for carotid endarterectomy should have carotid imaging within 1 week.

Carotid endarterectomy is also indicated following a non-disabling stroke. However, if the patient has had a disabling stroke there is no real benefit in them undergoing the procedure.

Carotid stenting is increasingly being used as an alternative to endarterectomy. This is a less invasive revascularisation strategy, and uses an embolic protection device. There seems to be a similar early risk of death or stroke, and similar long-term benefits. Risk is higher in elderly patients, possibly due to vascular tortuosity and calcification. The procedure is currently indicated in selected cases, such as restenosis.

* please note for this explanation we have used the North American Symptomatic Carotid Endarterectomy Trial (NASCET) criteria, as opposed to the European Carotid Surgery Trialists' Collaborative Group (ECST) criteria. See NICE guidelines for the difference - carotid

imaging reports will state which criteria are being used.

[Q: 4551] OnExamination 2012 -
Emergency Medicine

A 17-year-old woman is admitted by emergency ambulance. She has apparently taken a large overdose of her father's anti-hypertensive medication after he refused to allow her to see her boyfriend who is 21.

On admission to the emergency department she is hypotensive, with a BP of 80/55 mmHg, and a pulse of 28.

Investigations show

Hb 12.1 g/dl(13.5-18)

WCC $7.8 \times 10^9/L$ (4-10)

PLT $191 \times 10^9/L$ (150-400)

Na 139 mmol/l (134-143)

K 4.6 mmol/l (3.5-5)

Cr 85 $\mu\text{mol/l}$ (60-120)

Gluc 2.8 g/dl(7.0-11.0)

Her rate increases to 35 after 3 mg of atropine, but little improvement in BP is seen.

Which of the following is the next most appropriate step?

- 1- Further 1 mg atropine
- 2- IM adrenalin
- 3- IV adrenalin
- 4- IV glucagon
- 5- Temporary pacing

Answer & Comments

Answer: 4- IV glucagon

Glucagon is the conventional antidote for β -blocker overdose, the most likely cause of this patient's presentation. It reverses hypoglycaemia, and improves myocardial contractility and heart rate by stimulating production of cyclic AMP.

Doses of glucagon used are much higher than those conventionally used for reversing hypoglycaemia in diabetes, with a bolus of 3-10 mg being required, then 2-5 mg/hr by infusion.

[Q: 4552] OnExamination 2012 -
Emergency Medicine

A 35-year-old business man presents with anxiety and palpitations after 'snorting' cocaine. The patient denies any prior use and has also consumed some alcohol.

On examination, he is distressed and sweating with a temperature of 38°C , pulse of 138 beats per minute (regular) and a blood pressure of 216/110 mmHg. His ECG reveals a sinus tachycardia.

Which of the following is the most appropriate initial treatment for this man?

- 1- Dantrolene
- 2- Diazepam
- 3- Lidocaine
- 4- Propranolol
- 5- Verapamil

Answer & Comments

Answer: 2- Diazepam

Cocaine abuse is quite common and neurological and cardiovascular side effects predominate.

Delirium, hyperthermia, arrhythmias, myocardial and cerebral infarction are reported.

In this patient, the first consideration should be to establish adequate ventilation and support the circulation, and also to remove any residual cocaine from the nostrils.

Generally, the toxic effects of cocaine are short-lived and relate to sympathetic stimulation, as in this case with tachycardia, pyrexia and hypertension.

Initial treatment of cocaine poisoning involves intravenous administration of diazepam to control agitation, and cooling measures for hyperthermia.

Sedation with diazepam may also be appropriate initial therapy for hypertension and tachycardia in this situation since the excessive sympathetic tone is largely centrally mediated.

Control of anxiety and agitation with diazepam when combined with rapid cooling may also decrease heat production in hyperthermic patients.

If further treatment is required, an intravenous nitrate is particularly useful for associated coronary artery spasm.

[Q: 4553] OnExamination 2012 -
Emergency Medicine

A 45-year-old man attends the Emergency department with symptoms suggestive of community acquired pneumonia.

On examination he is pyrexial at 38.0°C and has a respiratory rate of 32/min, with a blood pressure of 85/55 mmHg.

Which of the following combination of features are not necessarily an indication for urgent hospital admission?

- 1- BP of 85/55 mmHg and respiratory rate of 32/min
- 2- BP of 85/55 mmHg and urea of 7.5 mmol/l
- 3- Confusion and BP of 85/55 mmHg
- 4- Pyrexia of 38.0°C and serum urea of 7.5 mmol/l
- 5- Respiratory rate of 32 and blood urea of 7.5 mmol/l

Answer & Comments

Answer: 4- Pyrexia of 38.0°C and serum urea of 7.5 mmol/l

This patient has community-acquired pneumonia (CAP).

The severity of each case of CAP should be assessed using the CURB-65 tool in conjunction with clinical judgement. Patients score 1 point for each of:

- Confusion
- Urea 7mmol/L
- Respiratory rate > 30/min
- Blood pressure: systolic <90 or diastolic < 60 mmHg
- Age > 65years

A CURB-65 score of 0 or 1 are at low risk of death, and can be treated at home if the social circumstances are compatible. A score of 2 usually indicates inpatient treatment is required, but hospital-supervised outpatient treatment can be considered. Patients who have a CURB-65 score of 3 or more are at high risk of death. Those with scores of 4 and 5 should be considered for treatment in a critical care unit (HCU, ITU).

In this question, option four has a CURB-65 score of 1 and outpatient treatment can therefore be considered. All the others are indications for inpatient treatment.

Clinical judgement must still however be used particularly if only one feature is present or if there is co-morbidity such as age over 50 years or chronic cardiac, respiratory or renal disease.

[Q: 4554] OnExamination 2012 -
Emergency Medicine

A 17-year-old male presents to the Emergency department after an overdose of alcohol and paracetamol.

He complained of abdominal discomfort and an intravenous infusion of N-acetylcysteine was commenced. 15 minutes later he

developed breathlessness, reported feeling flushed and developed a tachycardia.

Which of the following is most likely to have occurred?

- 1- A disulfiram-like (antabuse) reaction has occurred
- 2- The patient has developed pulmonary oedema
- 3- The patient has had a panic attack
- 4- The patient has received an overdose of N-acetylcysteine
- 5- The patient has received N-acetylcysteine previously

Answer & Comments

Answer: 5- The patient has received N-acetylcysteine previously

This patient is having an acute hypersensitivity reaction, the most common dose-independent adverse drug reaction.

It is caused by previous exposure and being sensitised to the drug.

The initial exposure induces the production of antibodies of immunoglobulin (Ig) E class, subsequent exposure induces an immunological reaction - anaphylaxis.

Some drugs can produce a similar pseudoallergic reaction on first exposure.

[Q: 4555] OnExamination 2012 - Emergency Medicine

A 42-year-old woman presents following an episode of confusion associated with vomiting and abdominal pain.

She had a one month history of weight loss and receives thyroxine for hypothyroidism which was diagnosed five years ago.

On examination she appeared unwell, with a temperature of 37.5°C and her blood pressure was 100/50 mmHg.

Investigations revealed:

Sodium 130 mmol/L (137-144)

Potassium 4.8 mmol/L (3.5-4.9)

Urea 7.6 mmol/L (2.5-7.5)

Glucose 2.7 mmol/L (3.0-6.0)

Free T₄ 9 pmol/L (10-22)

TSH 1 mU/L (0.4-5)

Which one of the following given intravenously would be the most appropriate initial management?

- 1- 10% dextrose infusion
- 2- Cefuroxime
- 3- Glucagon
- 4- Hydrocortisone
- 5- Tri-iodothyronine

Answer & Comments

Answer: 4- Hydrocortisone

This woman presents with classical features of Addison's disease and the most appropriate and lifesaving therapy is steroids given intravenously.

The abnormal thyroid function tests are often encountered in association with acute hypoadrenalism.

Giving thyroxine may actually exacerbate the condition.

[Q: 4556] OnExamination 2012 - Emergency Medicine

A 16-year-old girl is brought to the Emergency department after having taking drugs at a rave.

Which of the following suggests that she has taken Ecstasy (MDMA)?

- 1- Hypernatraemia
- 2- Metabolic acidosis
- 3- Pin-point pupils

4- Pyrexia

5- Respiratory depression

Answer & Comments

Answer: 4- Pyrexia

The features of ecstasy overdose include:

Hyperthermia

Hypertension

Hyponatraemia due to polydipsia associated with syndrome of inappropriate antidiuretic hormone (SIADH) and

Respiratory alkalosis.

Pin-point pupils suggest opiates.

[Q: 4557] OnExamination 2012 -
Emergency Medicine*Which of the following is correct concerning a precordial thump?*

- 1- Can be delivered up to twice during a cardiac arrest
- 2- Can be given following an unwitnessed cardiac arrest
- 3- Is more successful with pulseless VT than VF
- 4- Should be administered after a warning has been given to the patient
- 5- Should be aimed at the position of V4 on the anterior chest wall

Answer & Comments

Answer: 3- Is more successful with pulseless VT than VF

The 2010 ALS guidelines state that if a patient has a monitored and witnessed VF/VT arrest in hospital, three quick successive (stacked) shocks should be given. Chest compressions should be started immediately after the third, with a compression to ventilation ratio of 30:2 for 2 minutes.

A precordial thump can be successful if given within seconds of the onset of a shockable rhythm. Delivery should not delay calling for help, or accessing a defibrillator, but would be indicated here whilst awaiting the defibrillator. Chest compressions should start immediately if it is unsuccessful. Only one thump should be delivered over the lower third of the sternum. The ulnar edge of a tightly clenched fist is used to deliver a sharp impact from a height of about 20cm, then retract immediately (thereby creating an impulse-like stimulus). Repeating a precordial thump is not recommended.

Warning a patient who has arrested will serve little purpose.

It is important to remember that a precordial thump has a very low success rate for cardioversion. In general it delivers approximately 7-10 joules of energy, but this is operator dependent and references vary to this regard. There is more success with pulseless VT than with VF.

[Q: 4558] OnExamination 2012 -
Emergency Medicine

A 35-year-old woman with known seafood allergy presented after developing an itchy rash at a restaurant. She had widespread urticaria which spared her neck and face.

On examination, her blood pressure was 130/70 mmHg, pulse 95 bpm, respiratory rate 24/min and O₂ saturation 99% on air.

Intravenous hydrocortisone and intramuscular antihistamine have been given.

What is the next most appropriate step in the management of this patient?

- 1- Inhaled adrenaline
- 2- Intramuscular adrenaline
- 3- Intravenous adrenaline
- 4- Observe
- 5- Subcutaneous adrenaline

Answer & Comments

Answer: 4- Observe

Where there is a history of a typical allergic reaction, as here, current United Kingdom resuscitation guidelines suggest adrenaline if there is:

Stridor

Wheeze

Respiratory distress or

Clinical evidence of shock.

Reference:

A literature review in the BMJ includes a copy of the algorithm and a discussion of the evidence for adrenaline. BMJ 2003;327:1332-1335

[Q: 4559] OnExamination 2012 - Emergency Medicine

Which of the following is currently recommended as the drug of choice in treating refractory ventricular fibrillation or pulseless ventricular tachycardia?

- 1- Adenosine
- 2- Amiodarone
- 3- Bretylium
- 4- Lidocaine
- 5- Magnesium

Answer & Comments

Answer: 2- Amiodarone

300 mg of amiodarone made up to 20 ml with 5% dextrose given as an intravenous bolus is the drug of choice.

100 mg of lidocaine may be given intravenously when amiodarone is unavailable.

Historically 5 mg/Kg of bretylium was given, but it is no longer recommended.

[Q: 4560] OnExamination 2012 - Emergency Medicine

An 80-year-old gentleman attends the Emergency department with a stroke affecting his left arm and leg.

He has had radiotherapy to the neck and there is a lot of scarring present. Carotid scanning shows 70% stenosis in the symptomatic side.

Which statement is correct?

- 1- Carotid endarterectomy is contraindicated
- 2- Carotid endarterectomy should be performed
- 3- Carotid stenting is associated with lower rates of stroke than surgery
- 4- Carotid stenting is proven to be safer than carotid endarterectomy
- 5- Carotid stenting should be performed

Answer & Comments

Answer: 5- Carotid stenting should be performed

There is an indication for intervention in this patient.

As the patient has a hostile neck it would be difficult to perform a carotid endarterectomy but not contraindicated.

It would be preferable to perform carotid stenting if possible.

[Q: 4561] OnExamination 2012 - Emergency Medicine

A 90-year-old lady attends the Emergency department with a dense stroke affecting her left arm and leg.

She is hemiplegic and confused. A CT scan confirms that there is a right CVA. Carotid scanning shows stenosis of 75% on the right and 90% on the left.

What is the best course of action?

- 1- Admit but no surgical intervention

- 2- Bilateral carotid endarterectomy
- 3- Discharge and GP follow up
- 4- Urgent carotid endarterectomy on the left
- 5- Urgent carotid endarterectomy on the right

Answer & Comments

Answer: 1- Admit but no surgical intervention

This patient has a symptomatic carotid stenosis on the right that would be appropriate for surgery if this were a TIA or resolving stroke.

Unfortunately, with dense strokes, if there is no recovery, the benefits are greatly reduced due to end-organ damage.

Revascularisation would have the risk of reperfusion haemorrhage.

The benefit of endarterectomy is prevention of future stroke.

[Q: 4562] OnExamination 2012 -
Emergency Medicine

A 75-year-old lady attends the Emergency department with a stroke affecting her left arm and leg.

A CT scan confirms that there is a right CVA. Carotid scanning shows stenosis of 50% on the right and 90% on the left.

What is the best course of action?

- 1- Bilateral carotid endarterectomy
- 2- Discharge and GP follow up
- 3- Discharge and outpatient follow up
- 4- Urgent carotid endarterectomy on the left
- 5- Urgent carotid endarterectomy on the right

Answer & Comments

Answer: 3- Discharge and outpatient follow up

Carotid artery atherosclerosis is an important cause of ischaemic stroke. The left-sided neurological signs in this patient (which are

consistent with a TIA) indicate the symptomatic carotid is on the right side.

Carotid endarterectomy has been established as an effective treatment for both symptomatic patients and asymptomatic patients. It reduces the risk of disabling stroke or death by 48% in a person with severe symptomatic carotid stenosis (>70%) who has had a TIA. The peri-operative risk of disabling stroke or death is approximately 3%. Current UK guidelines recommend endarterectomy for symptomatic patients with greater than 70% stenosis, based on the North American Symptomatic Carotid Endarterectomy Trial which showed clear benefit. The endarterectomy should be performed as soon as the patient is fit for surgery, preferably within two weeks of a TIA.

The benefit is marginal for symptomatic patients with 50-69% stenosis, but may be greater in male patients. NICE recommends these patients are also considered for endarterectomy. There is significantly less benefit for asymptomatic patients, even those with greater than 60% stenosis. Patients with less than 50% stenosis should not be considered for carotid surgery.

Recurrent stenosis can occur in 1-20% of patients following endarterectomy, and re-operation is needed in 1-3% of cases. Ipsilateral strokes occur in 9% of patients following endarterectomy, and 26% of those treated with medical management alone (within 2 years).

All patients with suspected non-disabling stroke or TIA who are considered as candidates for carotid endarterectomy should have carotid imaging within 1 week.

Carotid endarterectomy is also indicated following a non-disabling stroke. However, if the patient has had a disabling stroke there is no real benefit in them undergoing the procedure.

Carotid stenting is increasingly being used as an alternative to endarterectomy. This is a less invasive revascularisation strategy, and uses an embolic protection device. There seems to be a similar early risk of death or stroke, and similar long-term benefits. Risk is higher in elderly patients, possibly due to vascular tortuosity and calcification. The procedure is currently indicated in selected cases, such as restenosis.

* please note for this explanation we have used the North American Symptomatic Carotid Endarterectomy Trial (NASCET) criteria, as opposed to the European Carotid Surgery Trialists' Collaborative Group (ECST) criteria. See NICE guidelines for the difference - carotid imaging reports will state which criteria are being used.

[Q: 4563] OnExamination 2012 -
Emergency Medicine

A 21-year-old man who has a past history of IV drug abuse presents 12 hours after taking an overdose of 480 mg of codeine and 30 g of paracetamol.

His blood pressure is 100/60 mmHg and he has pin-point pupils.

What is the most appropriate management for this patient?

- 1- 500ml 10% glucose IV over four hours
- 2- 1 litre normal saline IV over six hours
- 3- IV naloxone
- 4- IV flumazenil
- 5- Start N-acetylcysteine

Answer & Comments

Answer: 5- Start N-acetylcysteine

This patient presents 12 hours after taking a potentially fatally toxic dose of paracetamol.

In the circumstances provided in this question where there is an absence of data relating to pulse rate (as he is probably not in shock),

respiratory rate (reflecting respiratory depression) or blood glucose, the most appropriate intervention at this 12 hour time-point would be N-acetylcysteine.

The urgency of treatment is underlined by the fact that the incidence of hepatotoxicity is worse if treatment is delayed.

Trials of N-acetylcysteine suggest that the incidence of hepatotoxicity is 1% in those treated within eight hours as opposed to 46% in those treated after 16 hours.

[Q: 4564] OnExamination 2012 -
Emergency Medicine

A 17-year-old woman presented six hours after taking 30 g of paracetamol.

Which of the following factors is most likely to predict an increased risk of hepatotoxicity from the paracetamol?

- 1- Anorexia nervosa
- 2- Consumption of 20 units of alcohol since taking the paracetamol
- 3- Gilbert's disease
- 4- Ingestion of amitriptyline with the paracetamol
- 5- Smoking 20 cigarettes per day

Answer & Comments

Answer: 1- Anorexia nervosa

High risk groups in paracetamol overdose include:

malnourished patients (anorexia nervosa/bulimia nervosa)

patients taking enzyme inducing drugs (e.g. carbamazepine, phenytoin, rifampicin and St John's wort)

patients with induced liver enzymes due to chronic ethanol abuse

human immunodeficiency virus (HIV) positive patients.

More information

[Q: 4565] OnExamination 2012 -
Emergency Medicine

A 64-year-old woman presented 10 hours after ingestion of 12 g of quinine sulphate.

Which of the following is the most common characteristic clinical feature in this situation?

- 1- Blindness
- 2- Bradycardia
- 3- Hyperacusis
- 4- Hyperglycaemia
- 5- Hypotension

Answer & Comments

Answer: 1- Blindness

The major toxic effects of quinine are on the nervous system, in particular the optic and auditory nerve. It is also particularly toxic on retinal photoreceptor cells, and causes vasoconstriction and spasm of the retinal artery. Blurred vision can proceed to complete blindness, which is characteristic of overdose. Initial signs are narrowing of the retinal arterioles on fundoscopy. Later there is retinal oedema, and the pupils become dilated and unresponsive to light.

Effects on the auditory nerve may cause tinnitus and deafness, but not hyperacusis.

Initially quinine causes generalised stimulation of the central nervous system, leading to tachycardia, fever, delirium and tachypnoea. In severe overdose it can then cause myocardial depression, peripheral vasodilation and widened QRS with prolonged QTc and risk of VT, torsade and VF.

In addition, renal failure, haemolytic anaemia and gastrointestinal disturbance can develop. At very high plasma levels, sinoatrial block and high-degree atrioventricular block may be seen. Hypotension may occur secondary to

quinine's alpha-blocking effect, but is not as characteristic as blindness.

Additional features include nausea, vomiting, headache, seizures, fatigue, tremor and ataxia. Hyperglycaemia is not characteristic.

Management is with activated charcoal and gastric lavage, if presentation is early enough. Bradycardia can be treated with atropine or pacing. Bicarbonate is considered for a prolonged QRS (>120ms), aiming for a pH of 7.45-5. Haemodialysis can also be used to clear the quinine. There is no specific treatment for visual disturbance.

[Q: 4566] OnExamination 2012 -
Emergency Medicine

A 20-year-old man presented after ingesting a drug at a party. Investigations revealed a serum creatine kinase of 10,000 IU/l (NR 24-195).

Which one of the following drugs is most likely to have been responsible?

- 1- Cannabis
- 2- Diazepam
- 3- Ecstasy (MDMA)
- 4- Gamma hydroxybutyrate (GHB)
- 5- Ketamine

Answer & Comments

Answer: 3- Ecstasy (MDMA)

Symptoms of an acute MDMA toxic reaction include:

- Agitation
- Tachycardia
- Hypertension
- Dilated pupils
- Trismus
- Sweating

whereas the more severe cases may be characterised by:

Hyperthermia

Disseminated intravascular coagulation (DIC)

Rhabdomyolysis

Acute renal failure.

In more severe cases, elevated creatine kinase levels are often present, with levels as high as 555,000 IU/l being reported.

Neither GHB nor ketamine are associated with elevated CK levels.

Phencyclidine (PVP) is another drug which may cause an elevated CK in overdose.

massive overdose and usually associated with lactic acidosis.

It is too early to carry out paracetamol levels as these should be carried out at four hours.

Although he states that he has taken 18 g of paracetamol this may not be the case and he may not require N-acetyl cysteine. You can wait. In fact the benefit of N-acetyl cysteine is maximum as long as it is given within eight hours of ingestion. Its benefit extends up to 24 hours.

An elevated international normalised ratio (INR) gives an indication of hepatocellular damage and again this will not be seen at presentation of paracetamol overdose.

[Q: 4567] OnExamination 2012 -
Emergency Medicine

A youth worker, aged 40, presents to the Emergency department with vomiting.

On detailed questioning, he states that he has taken about 36 paracetamol tablets two hours previously. He is vomiting profusely with a blood pressure of 90/60 mmHg.

Which of the following measures would be the most appropriate immediate step in the management of this patient?

- 1- Coagulation screen
- 2- IV fluids
- 3- IV N-acetyl cysteine
- 4- Oral methionone
- 5- Paracetamol levels

Answer & Comments

Answer: 2- IV fluids

The most pressing issue in this patient is resuscitation as he is vomiting and is hypotensive.

It is unusual to see such hypotension in paracetamol overdose but is feasible in a

[Q: 4568] OnExamination 2012 -
Emergency Medicine

In adult basic life support which of the following is the correct ratio of chest compressions to ventilations?

- 1- 5 to 1
- 2- 8 to 1
- 3- 10 to 1
- 4- 15 to 2
- 5- 30 to 2

Answer & Comments

Answer: 5- 30 to 2

Fifteen compressions to two breaths was the recommended ratio regardless of the number of rescuers performing basic life support, but the recent guidelines now suggest 30:2.

[Q: 4569] OnExamination 2012 -
Emergency Medicine

A 72-year-old lady presented after taking an overdose of a sustained-release propranolol preparation.

She has a pulse of 40 bpm and a BP of 90/60 mmHg.

She was given atropine by the Emergency department staff but there has been little response.

Which of the following is the most appropriate treatment?

- 1- Atropine
- 2- Glucagon
- 3- Haemodialysis
- 4- Noradrenaline
- 5- Salbutamol

Answer & Comments

Answer: 2- Glucagon

'For cases of β -blocker poisoning where symptomatic bradycardia and hypotension are present, high-dose glucagon is considered the first-line antidote.' Am J Health Syst Pharm. 2006 Oct 1;63(19):1828-35

[Q: 4570] OnExamination 2012 - Emergency Medicine

In most cardiac arrest situations 1mg of adrenaline (epinephrine) is given intravenously every three minutes.

What is the correct volume and concentration of the adrenaline?

- 1- 0.1 ml of 1 in 100
- 2- 1 ml of 1 in 1000
- 3- 10 ml of 1 in 1000
- 4- 1 ml of 1 in 10,000
- 5- 10 ml of 1 in 10,000

Answer & Comments

Answer: 5- 10 ml of 1 in 10,000

A 1 mg dose of adrenaline (epinephrine) would be administered with 0.1 ml of 1 in 100, 1 ml of 1 in 1000 and 10 ml of 1 in 10,000.

However, 10 ml of 1 in 10,000 is the recommended dose and concentration and is

considered the optimum volume of adrenaline during cardiac arrest, and is recommended by the UK Resuscitation Council.

[Q: 4571] OnExamination 2012 - Emergency Medicine

A 51-year-old homeless man is seen in the Emergency department with a two day history of a painful left little finger. He speaks little English and a history is difficult to establish.

On examination he has fusiform swelling of the finger with a small laceration on the pulp which looks old. The finger is held in flexion, there is pain on passive extension of the finger and tenderness on the volar aspect of the finger. Examination of the other fingers was unremarkable.

What is the diagnosis?

- 1- Acute paronychia
- 2- Cellulitis
- 3- Flexor sheath infection
- 4- Interphalangeal joint septic arthritis
- 5- Palmar space infection

Answer & Comments

Answer: 3- Flexor sheath infection

Flexor sheath infection or infectious flexor tenosynovitis results from a microorganism (commonly *Staphylococcus aureus*) multiplying in the closed space of the flexor tendon sheath and culture-rich synovial fluid medium. This is usually secondary to penetrating trauma to the hand.

The septic process and this inflammatory reaction within the tendon sheath quickly interfere with the gliding mechanism, leading to adhesions and scarring. The ultimate consequences are tendon necrosis, disruption of the tendon sheath, and digital contracture.

Physical examination reveals Kanavel signs of flexor tendon sheath infection, which are:

Finger held in slight flexion

Fusiform swelling

Tenderness along the flexor tendon sheath, and

Pain with passive extension of the digit.

Treatment is urgent surgical washout of the flexor sheath and intravenous antibiotics.

Septic arthritis of the interphalangeal joints is extremely rare and usually presents with pain, swelling, and reduced range of motion of an individual joint.

Acute paronychia often presents with a history of minor trauma to the fingertip. The presenting complaints are pain, tenderness, and swelling in one of the lateral folds of the nail and not along the finger.

Palmar space infection is an infection of one or all the fascial compartments of the hand. It may result from untreated flexor sheath infection. It presents with pain and swelling of the entire hand with pain on massive movement of all digits. The patient in the scenario experienced pain on movement of the little finger only.

Cellulitis of the hand presents with generalised swelling, erythema and pain. The skin looks shiny and is warm to touch. Generally there is no exacerbation of pain with finger movement.

[Q: 4572] OnExamination 2012 -
Emergency Medicine

An 80-year-old man attends the Emergency department with falls.

On history taking you find that he had a stroke affecting his left arm and leg a year ago. A CT scan confirms that there is a right CVA. Carotid scanning shows stenosis of 80% on the right and 90% on the left.

What is the best course of action?

1- Bilateral carotid endarterectomy

2- Discharge and GP follow up

3- Discharge and outpatient follow up

4- Urgent carotid endarterectomy on the left

5- Urgent carotid endarterectomy on the right

Answer & Comments

Answer: 3- Discharge and outpatient follow up

This is a difficult question. The gentleman has obviously had a stroke which could be attributed to his carotid atherosclerosis. However, it is a significant period since he had his symptoms. The benefit of carotid endarterectomy is therefore less clear. It is not indicated urgently, and should be discussed with a specialist to weigh up the risks and benefits.

[Q: 4573] OnExamination 2012 -
Emergency Medicine

A gentleman attends the Emergency department with a stroke.

On the ward his stroke is starting to resolve and the likely diagnosis is a transient ischaemic attack (TIA).

Which is the next best course of action?

1- CT head and duplex as an outpatient

2- Discharge and follow up in TIA clinic

3- Discharge and GP follow up

4- Urgent carotid endarterectomy

5- Urgent CT head and carotid duplex whilst inpatient

Answer & Comments

Answer: 5- Urgent CT head and carotid duplex whilst inpatient

NICE guidelines for stroke and TIA treatment state that a patient with a TIA should receive a CT / MRI head and carotid duplex within a week and then surgery if necessary within two weeks.

Department of Health guidelines go further and state that surgery should occur within 48 hours of arrival.

[Q: 4574] OnExamination 2012 -
Emergency Medicine

A 22-year-old female is admitted very distressed and short of breath.

Examination reveals a respiratory rate of 35/min, a pulse of 120 beats per minute, a blood pressure 110/70 mmHg, oxygen saturations of 90% and a peak expiratory flow rate <50% predicted.

The emergency medical services have administered salbutamol 5 mg (twice) and face mask oxygen.

Which of the following is the most appropriate next action in this patient?

- 1- Arterial blood gas analysis
- 2- Intensive care referral
- 3- Oxygen 35%
- 4- Prednisolone 40 mg
- 5- Salbutamol 5 mg and ipratropium bromide 0.5 mg

Answer & Comments

Answer: 5- Salbutamol 5 mg and ipratropium bromide 0.5 mg

This patient fits the criteria for acute severe asthma. In such cases β_2 -agonists should be administered as soon as possible, preferably nebulised driven by oxygen. Repeat doses should be given at 15-30 minute intervals, or continuous nebulisation can be used where there is inadequate response to bolus therapy. Nebulised ipratropium bromide should be added for patients with acute severe or life threatening asthma, or those with a poor initial response. Its addition produces significantly greater bronchodilation than a β_2 -agonist alone.

Oxygen should be given to maintain saturations at 94-98%. Patients with saturations less than 92% on air should have an ABG to exclude hypercapnia. However, starting treatment should not be delayed to do the ABG. Initially high-flow oxygen is used, and then weaned to maintain adequate saturations. Unless you suspect COPD there isn't a need to be cautious with oxygen therapy.

Steroids reduce mortality, relapses, subsequent hospital admission and requirement for β_2 -agonists¹. The earlier they are given in the attack, the better the outcome. A dose of 40-50mg should therefore be given once oxygen and nebuliser therapy has been established. This should be continued for 5 days, or until recovery, and can then be stopped abruptly unless the patient has taken long-term oral corticosteroids.

Failure to respond to the above treatment steps may warrant the use of intravenous magnesium sulphate and aminophylline. However, these should not be used without discussion with your senior colleagues.

Intensive care is indicated for patients with severe acute or life threatening asthma who are failing to respond to therapy. Consider it in patients with deteriorating peak flow, persisting or worsening hypoxia, hypercapnia, acidosis, exhaustion or altered conscious state. All patients who are transferred to an intensive care unit should be accompanied by a doctor who can intubate if necessary.

As an aside, chest radiographs are not indicated unless you suspect pneumothorax or consolidation, or there is life-threatening asthma, a failure to respond to treatment or a need for ventilation.

[Q: 4575] OnExamination 2012 -
Emergency Medicine

A 18-year-old female is brought to the

Emergency department unconscious after having taken an overdose.

On examination she has a Glasgow coma score of 6, a respiratory rate of eight breaths per minute, a heart rate of 52 beats per minute and her blood pressure is 84/62 mmHg. Her pupils are small but are reactive to light, muscle tone is reduced and plantar responses are flexor.

Which of the following is she most likely to have taken in overdose?

- 1- Diazepam
- 2- Dihydrocodeine
- 3- Diphenhydramine
- 4- Ecstasy (MDMA)
- 5- Methanol

Answer & Comments

Answer: 2- Dihydrocodeine

Dihydrocodeine is an opiate analgesic and when taken in overdose has a number of toxic effects. It acts as a respiratory depressant leading to reduced respiratory rate. It can cause bradycardia and hypotension in large doses. Pupillary constriction is a diagnostic feature in opiate overdose.

It is also a central nervous system depressant and therefore causes coma in overdose.

Benzodiazepines and antihistamines tend not to have the same cardiorespiratory effects as opiates.

MDMA is a stimulant and can cause delirium, convulsions and ventricular arrhythmias.

Diazepam would be less likely here due to the bradycardia and the hypotension.

[Q: 4576] OnExamination 2012 - Emergency Medicine

An 18-year-old woman presents three days after allegedly taking 50 paracetamol tablets (25 g).

Which of the following tests measured at this time point would be most helpful in determining the outcome?

- 1- ALT concentration
- 2- Bilirubin concentration
- 3- Creatinine concentration
- 4- Paracetamol concentration
- 5- Prothrombin time

Answer & Comments

Answer: 5- Prothrombin time

The patient has ingested a seriously toxic dose of paracetamol.

The best determinant of this risk at 72 hours would be a prolonged prothrombin time.

Paracetamol concentrations would be rather meaningless at this point in time, and irrespective, she should be treated with N-acetylcysteine.

There are four phases of paracetamol overdose:

Phase 1 (0-24 hours)

Asymptomatic

Anorexia

Nausea or vomiting

Malaise

Subclinical rise in serum aspartate transaminase (AST) - 12 hours post ingestion.

Phase 2 (18-72 hours)

Right upper quadrant abdominal pain, anorexia, nausea, vomiting

Continued rise in serum transaminases levels (note this is the time slot for our patient with the alanine transaminase [ALT] rises).

Phase 3 (72-96 hours)

Centrilobular hepatic necrosis with continued abdominal pain

Jaundice

Coagulopathy

Hepatic encephalopathy

Nausea and vomiting

Renal failure

Fatally rising international normalised ratio/prothrombin time (INR/PT) from three days.

Phase 4 (Four days to three weeks)

Complete resolution of symptoms

Complete resolution of organ failure.

[Q: 4577] OnExamination 2012 -
Emergency Medicine

A 30-year-old man is admitted three hours after taking an overdose of amitriptyline and diazepam.

On examination he was drowsy with a Glasgow coma scale of 8, he had a pulse of 140 beats per minute, a blood pressure of 114/88 mmHg and dilated pupils. His oxygen saturation was 90% on room air.

What is the most appropriate initial action for this patient?

- 1- Activated charcoal
- 2- CT head scan
- 3- ECG
- 4- IV atenolol
- 5- IV flumazenil

Answer & Comments

Answer: 3- ECG

Obviously this patient with a markedly reduced GCS needs basic resuscitation. However, the most appropriate initial action specifically for his overdose would be to get

the investigations done as quickly as possible - arterial blood gases and ECG, as the latter may show QRS widening and merit treatment.

Gastric decontamination with lavage and activated charcoal is used if the patient presents within one hour of overdose.

Treatment with bicarbonate is also advocated as this patient displays features of severe TCA overdose. The aim is to get the pH >7.4.

He does not need a CT scan as the symptoms are typical of tricyclic overdose.

Flumazenil is not appropriate for this patient as the symptoms are mostly of TCA overdose nor is IV atenolol appropriate for the arrhythmias. A number of studies have shown that in cases of mixed benzodiazepine and tricyclic overdose, flumazenil can unmask the convulsant properties of TCAs and increase the severity of arrhythmias induced by them.

The arrhythmias induced by TCAs often respond to sodium bicarbonate, but if they don't intravenous glucagon can be used. Adrenaline and magnesium sulphate can also be used.

[Q: 4578] OnExamination 2012 -
Emergency Medicine

A 75-year-old man was admitted after being found collapsed in a garden shed surrounded by a number of empty containers.

On clinical examination the patient had small pupils, a heart rate of 50 beats per minute, and was frothing at the mouth.

What is the most likely diagnosis?

- 1- Creosote poisoning
- 2- Glyphosate poisoning
- 3- Organophosphorus poisoning
- 4- Paraquat poisoning
- 5- Pyrethroid poisoning

Answer & Comments

Answer: 3- Organophosphorus poisoning

The patient has cholinergic features with a relative bradycardia, small pupils and increased salivation. This is highly suggestive of organophosphorus poisoning which is an anticholinesterase, thus prolonging the effects of acetylcholine.

Paraquat is associated with nausea, vomiting and diarrhoea with ulceration.

Creosote is a petroleum based substance and would not have such an effect.

Glyphosate herbicides produce nausea, vomiting and diarrhoea with a caustic effect in the mouth.

Pyrethroid is an insecticide and poisoning is rare but associated with coma, convulsions and pulmonary oedema.

[Q: 4579] OnExamination 2012 - Emergency Medicine

An 18-year-old woman is admitted after taking drugs at a night club.

Which of the following features suggest she had taken Ecstasy (MDMA)?

- 1- A pyrexia of 40°C
- 2- Hyponatraemia
- 3- Hypokalaemia
- 4- Metabolic acidosis
- 5- Respiratory depression

Answer & Comments

Answer: 1- A pyrexia of 40°C

Features of the amphetamine MDMA abuse include:

Hyponatraemia
Tachycardia
Hyperventilation

Hyperthermia.

[Q: 4580] OnExamination 2012 - Emergency Medicine

A 19-year old girl has been brought to the Emergency department by her friends following a night out at a party. Her friends comment that she has been talking by herself about 'irrelevant things'. She seems agitated and restless.

On examination, her reflexes are increased and an electrocardiogram (ECG) demonstrates ventricular ectopics.

What kind of substance abuse do you suspect at this point?

- 1- Alcohol
- 2- Barbituate
- 3- Cannabis
- 4- Ecstasy
- 5- Glue sniffing

Answer & Comments

Answer: 4- Ecstasy

This is a case of ecstasy overdose.

Ecstasy (3,4-methylenedioxymethamphetamine, MDMA) stimulates the central nervous system.

It causes:

Increased alertness and self-confidence

Euphoria

Extrovert behaviour

Increased talkativeness with rapid speech

Lack of desire to eat or sleep

Tremor

Dilated pupils

Tachycardia and

Hypertension.

More severe intoxication is associated with:

Excitability

Agitation

Paranoid delusions

Hallucinations with violent behaviour

Hypertonia and

Hyperreflexia.

Convulsions, rhabdomyolysis, hyperthermia, and cardiac arrhythmias may also develop.

In severe cases of MDMA poisoning:

Hyperthermia

Disseminated intravascular coagulation

Rhabdomyolysis

Acute renal failure and

Hyponatraemia

are observed.

Hepatic damage has also been reported.

Rarely, poisoning due to amphetamines may result in intracerebral and subarachnoid haemorrhage and acute cardiomyopathy; these complications may be fatal.

Hyperthyroxinaemia may be found in chronic amphetamine users.

[Q: 4581] OnExamination 2012 -
Emergency Medicine

A 27-year-old female presents to the surgical intake with abdominal pain and a five day history of vomiting.

Over the last three months she has also been aware of a 6 kg weight loss.

On examination, she is pale, has a temperature of 38.5°C, blood pressure of 90/60 mmHg and pulse rate of 130 in sinus rhythm. The chest is clear on auscultation but

she has a diffusely tender abdomen with no guarding. Her BM reading is 2.5.

Initial biochemistry is as follows:

Sodium 124 mmol/l (137-144)

Potassium 6.0 mmol/l (3.5-4.9)

Urea 7.5 mmol/l (2.5-7.5)

Creatinine 78 µmol/l (60-110)

Glucose 2.0 mmol/l (3.0-6.0)

What is the probable diagnosis?

1- Abdominal migraine

2- Acute appendicitis

3- Acute cholecystitis

4- Addison's disease

5- Insulinoma

Answer & Comments

Answer: 4- Addison's disease

This patient has clinical features of hypoadrenal crisis with abdominal pain, vomiting and shock with hypoglycaemia, hyponatraemia and hyperkalaemia. In the UK this is commonly due to autoimmune destruction of the adrenal glands (Addison's disease). Rarer causes are TB, HIV adrenal haemorrhage or anterior pituitary disease. Patients classically present with weight loss, abdominal pain, lethargy and nausea and vomiting. Addison's disease is also associated with oral pigmentation (due to excess ACTH and therefore MSH), and other autoimmune disease (including thyroid disease and vitiligo).

Patients such as this need emergency fluid resuscitation, steroid administration (prior to this urgent cortisol measurement), and careful search for occult infection.

None of the other options explain the biochemical findings.

[Q: 4582] OnExamination 2012 -
Emergency Medicine

A 16-year-old male is brought to the Emergency department with a Glasgow coma scale (GCS) rating of 3/15.

Within 10 minutes he regained consciousness with a GCS of 15/15, is sitting up and talking.

What is he likely to have taken?

- 1- Inhaled solvent glue
- 2- Smoked heroin
- 3- Smoked marijuana
- 4- Snorted cocaine
- 5- Taken ecstasy

Answer & Comments

Answer: 1- Inhaled solvent glue

This patient was markedly comatose on arrival but quickly regains consciousness. This suggests a short acting (probably) inhaled anaesthetic-like agent - glue.

Marijuana would not be expected to produce this level of coma and the effects of cocaine would last much longer.

The inhaled solvents, due to their lipophilicity, are rapidly absorbed through the lungs and then quickly distributed to the brain and other organs. The effects therefore appear within minutes of inhalation.

Typical substances that are inhaled include toluene aromatic hydrocarbons and butane.

[Q: 4583] OnExamination 2012 -
Emergency Medicine

A 14-year-old boy bangs heads with an opponent during an unofficial football game. He is knocked out for 30 seconds and is amnesic for the event. He recovers quickly and continues playing.

The following day he complains of headache, begins vomiting then loses consciousness.

He had a full term normal delivery with no neonatal complications. His immunisations are up to date. There is no family or social history of note.

On examination he responds only to deep pain. He is afebrile with respiratory rate of 10/min (irregular), pulse of 40/min. He has a large bruise in the right temporal area.

What is the most likely diagnosis?

- 1- Cerebral contusion
- 2- Contracoup injury
- 3- Extradural haematoma
- 4- Subdural haematoma
- 5- Parietal skull fracture

Answer & Comments

Answer: 4- Subdural haematoma

The history is of a closed head injury, followed by a lucid period followed by decreasing level of consciousness.

The time course suggests a subdural haematoma where there is venous bleeding which accumulates in the subdural area causing raised intracranial pressure. This may in time progress to tonsillar herniation.

Epidural haematoma (extradural haemorrhage), typically from a torn middle meningeal artery and associated with skull fracture, accumulates much more rapidly. There may be apparent recovery from the initial concussion, but deterioration is usually within 15-30 minutes.

[Q: 4584] OnExamination 2012 -
Emergency Medicine

A 55-year-old male presented six hours after taking an overdose of lithium tablets which had been prescribed for a bipolar affective disorder.

On examination he was tremulous, had suffered a convulsion and had a Glasgow

coma scale of 12/15. His serum lithium concentration was 5.0 mmol/L (0.5-1.0)

What is the most appropriate management of this patient?

- 1- Activated charcoal
- 2- Forced alkaline diuresis
- 3- Furosemide 100 mg intravenously twice daily
- 4- Haemodialysis
- 5- Measure lithium concentration in 2 hours

Answer & Comments

Answer: 4- Haemodialysis

The patient has a severe lithium overdose as reflected by markedly elevated lithium concentrations and features of impaired consciousness, tremor and seizures.

This needs urgent management.

Activated charcoal does not bind lithium effectively and is therefore ineffective except where co-ingestion of other poisons is suspected.

Haemodialysis is the mainstay of treatment for acute lithium toxicity.
